ACKNOWLEDGEMENTS

I wish to express my gratitude to my late supervisor Dr Dez Barbara. His encouragement, intelligence and wit had a high impact on both my work and the way of thinking. I could not have wished for better supervisor.

Dr Sreenivasaprasad, my first supervisor, I would like to thank for giving me the opportunity to work with him and his support during the first year of my studies. I would also like to thank Dr John Clarkson and Dr Andrew Taylor for the valuable discussion over the years and helping me through the last months of my PhD. Dr Jeff Peters and Dr Charles Lane, my external supervisors, I would like to thank for their encouragement.

I am grateful for Dr Richard Harrison's, Riccardo Baroncelli's and Jeanette Shelby's help with genome sequencing and assembly. I am thankful for the statistical support from Dr Julie Jones and Dr Andrew Mead.

I wish to thank Defra for funding, Alaister Findlay, Andrew Richardson and the onion growers for useful discussion and help with my experiments, a great number of researchers and institutes for providing me with their isolates.

I would like to thank the many people I have worked with over the past 4 years, particularly Andrew Armitage and Claire Grant, their humour, encouragement and help with bits and bobs in the lab has been invaluable. I am grateful to Dr Ralph Noble, Andreja Dobrovin-Pennington and Dr Emma Coventry for their kind encouragement and great field trips together. I also like to thank the support staff for helping me with the glasshouse experiments.

Gratitude is extended to the external examiner, Prof. Richard Cooper, and to the internal examiner, Prof. Eric Holub, for their criticism and helpful comments.

Finally, by no means last, I wish to thank my Mum, Sister and Dad who always encourage me, and the little group of close friends, Krisztina, Mate and Jon, their help, encouragement, nagging has been invaluable during my PhD. Better family and friends could not be asked for.

“Fungi are more closely related to the mycologists that study them than to the plants on which they occur. “

W.F.O. Marasas – *Fusarium* taxonomist

DECLARATION

I declare that the material contained in this thesis is obtained from my own work which has not been submitted to another university for a degree and has not been published previously. Any data, materials and information obtained from external sources, published or unpublished, are identified as such and referenced accordingly.

Viktoria Vágány

ABSTRACT

The primary aim of this project was to identify and characterise *Fusarium* species associated with the basal rot of *Allium* species and internal fruit rot of sweet peppers in the UK. The secondary objective was to develop quick molecular markers to identify *Fusarium oxysporum* f. sp. *cepae* (FOC) causing onion basal rot. Isolates representing diverse *Fusarium* species taken from onions, garlic, shallot and leeks obtained from different production and processing sites in the UK were collected. *F. proliferatum* was found for the first time to be a causal agent of onion basal rot in the UK, but *F. oxysporum* was by far the most common species and *F. oxysporum* isolates belonged to at least two different genotypes based on a sequence comparison of several "housekeeping" genes, and overall, appeared to be polyphyletic. None of the housekeeping genes studied correlate with pathogenicity. Secreted in xylem (*SIX*) genes offer more promise for the specific identification of *F. oxysporum* formae speciales (Lievens *et al*., 2009a) and a homologue of the *SIX7* gene was found only in a few FOC isolates suggesting that *SIX7* is not absolutely necessary for pathogenicity. Whole genome sequencing of a FOC isolate was carried out in order to understand pathogenicity and identify novel effector genes. This work revealed the presence of further homologues of published *SIX* genes, namely *SIX3*, *SIX5* and *SIX9*. The presence of *SIX3* and *SIX5* has only been reported from *F. oxysporum* f. sp. *lycopersici* previously. Additionally, screening of eleven new candidate effector genes suggested that FOC isolates have different gene sets which correspond to the continuous variation of aggressiveness found within the FOC population. *Fusarium lactis, F. proliferatum* and *F. solani* were identified in association with internal fruit rot of sweet pepper obtained from three different production sites in the UK.

LIST OF ABBREVIATIONS

aa	amino acid
AFLP	Amplified fragment length polymorphism
bp	base pair
DNA	Deoxyribonucleic acid
FOC	*Fusarium oxysporum* f. sp. *cepae*
FOL	*Fusarium oxysporum* f. sp. *lycopersici*
f. sp.	Forma specialis (singular)
ff. spp.	Formae speciales (plural)
IGS	Intergenic spacer region
ITS	Internal transcribed spacer region
kb	Kilo base pair
LB	Luria-Bertani medium
l.s.d.	least significant difference
MLST	Multi locus sequence typing
MPC	Mobile pathogenicity chromosome
mtDNA	Mitochondrial DNA
PCR	Polymerase chain reaction
PDA	Potato dextrose agar
RAPD	Random amplified fragment length polymorphism
rDNA	Ribosomal deoxyribonucleic acid
REML	Residual maximum likelihood
RFLP	Restriction fragment length polymorphism
RNA	Ribonucleic acid
RPB2	RNA polymerase II subunit
rRNA	Ribosomal RNA
SCAR	Sequence characterized amplified region
SIX	Secreted in xylem
sp.	Species (singular)
spp.	Species (plural)
SSR	Simple sequence repeat
TEF	Translational elongation factor 1α subunit
VCG	Vegetative compatibility group

CHAPTER 1

GENERAL INTRODUCTION

1.1 *Fusarium* genus

The *Fusarium* genus comprises a wide variety of filamentous fungi recognised as plant, animal and human pathogens and soil saprophytes (Leslie and Summerell, 2006). The members of this genus include the causal agents of some of the most economically devastating plant diseases such as head blight of wheat and Panama disease of bananas (Summerell *et al*., 2010). Some fusaria cause animal and human diseases directly, e.g. keratitis or indirectly by producing mycotoxins such as trichothecenes and fumonisins (Moretti, 2009). Fusaria are widely distributed around the world and can survive for a long time in all types of soils as they are able to utilise a wide range of organic matter (Nelson *et al*., 1981).

Many plant species have at least one *Fusarium*-associated disease and the types of symptoms induced include root or stem rots, cankers, wilts, fruit or seed rots, head blight, and leaf diseases depending on the developmental stages, host plants and *Fusarium* species involved (Moretti, 2009). It is not uncommon for opportunistic species of the genus to colonise plants as a part of a complex of *Fusarium* species. Head blight of cereal crops is caused by several species including, but not limited to, *Fusarium graminearum, F. avenaceum, F. culmorum,* and *F. poae* (Nicholson *et al*., 2003). Head blight of wheat is the most economically devastating plant disease caused by the *Fusarium* species, as wheat is the third most produced cereal after maize and rice in terms of production yield (FAOSTAT, 2010) and it causes severe production losses worldwide, which may be as high as 50 percent (Gilchrist and Dubin, 2002).

F. graminearum, F. proliferatum, F. lactis and several other species can produce a variety of mycotoxins (e.g. trichothecenes and fumonisins) that are

associated with plant disease, as well as with cancer and other growth defects in humans and animals (Masuda *et al*., 2007; Gelderblom *et al*., 1988). Consumption of cereal crops contaminated by trichothecenes can cause chronic and fatal toxicosis in humans and animals through the inhibition of protein synthesis (Rotter *et al*., 1996). Fumonisins are not only capable of increasing the likelihood of cancer, but are hepatotoxic, nephrotoxic and neurotoxic (Stockmann-Juvala and Savolainen, 2008). *F. solani* and *F. oxysporum* species may cause opportunistic infections such as fusariosis, in immunocompromised humans and animals (O'Donnell *et al*., 2004). Ocular infections, keratitis, by *F. solani and F. oxysporum* have also been observed recently among contact lens users (Chang *et al.,* 2006).

Many fusaria serve a beneficial function in soil habitats as saprophytes degrading plant debris or preventing plant diseases (Edel *et al*., 1997). *Fusarium oxysporum, F. solani, F. culmorum* and *F. redolens* are frequently isolated from soil (Balmas *et al*., 2010).

Additionally, some species may be used for human nourishment; *Fusarium veneatum* myco-protein, for example, is produced industrially and marketed as Quorn (Wiebe, 2002). Furthermore, *F. oxysporum* was used for the synthesis of silver nanoparticles (Ahmad *et al*., 2003).

1.2 Classification of *Fusarium* genus

The *Fusarium* genus was introduced by Link in 1809 and the name refers to the characteristic spindle-shaped (Latin *fusus* means spindle) macroconidia. The genus *Fusarium* (anamorph) belongs to the *Ascomycota* phylum, *Sordariomycetes* class, *Hypocreales* order, and is also known by its teleomorphs *Gibberella* and *Nectria* (Leslie and Summerell, 2006). During the last 200 years the number of

Fusarium species has varied from 5 to 1000 based on the taxonomical systems used; at the moment more than 80 *Fusarium* species are recognised (Leslie & Summerell, 2006).

Discrimination of *Fusarium* species was traditionally based on morphological characters (morphological species recognition) that enabled the identification of some of the most important pathogens (Moretti, 2009). However, the genus lacks reliable morphological characters (Geiser *et al.*, 2004), and it is therefore very difficult for researchers with little experience to characterise *Fusarium* species based purely on morphological traits. For example, differences in the shape and size of the macroconidia and microconidia can be subjective and depend upon the environment in which they are produced (Leslie and Summerell, 2006).

Fusarium species can be recognized based on their ability to actually or potentially interbreed with other members of the population (biological species recognition), rather than their morphological appearance (Mayr, 1942). For instance, the *Gibberella fujikuroi* species complex was divided into at least eleven different biological species or mating populations (Britz *et al*., 1999; Klaasen and Nelson, 1996; Leslie, 1991; Zeller *et al*., 2003; Geiser *et al*., 2005). On the other hand, it is difficult to apply the concept of biological species to fusaria because some lacks sexual reproduction (Kerenyi *et al*., 1999). Although several *Fusarium* species, i.e. *F. solani* and *F. graminearum*, mate in either a homothallic or heterothallic manner, important pathogenic species, including *F. avenaceum*, *F. culmorum* and *F. equiseti*, have no known sexual stage.

Phylogenetic analyses (phylogenetic species recognition) can be useful to resolve species level identification of fungi without a known sexual stage. Many phylogenetic studies use DNA sequences of one or two loci of a few isolates, which

can be misleading. For example, the ribosomal internally transcribed spacer (ITS) can have non-orthologous sequences of the ITS2 region in individual representatives of the *Gibberella* clade (O`Donnell and Cigelnik, 1997). Because of these issues, the most widely accepted concept among mycologists and fungal biologists for *Fusarium* and other fungal species boundaries is a phylogenetic approach, based on the concordance of multiple gene genealogies when compared with morphology and reproductive behaviour (Taylor *et al*., 2000). For example, O'Donnell and co-workers used nuclear 28S rDNA, mitochondrial small subunit of ribosomal rDNA (mtSSU), and β-tubulin gene sequences to resolve species boundaries within the *Gibberella fujikuroi* species complex (O'Donnell *et al*., 1998b). In this study, 46 phylogenetic species were predicted, eleven of which were previously identified based on biological species recognition, but 23 of which were proposed to be new species. This shows that phylogenetics can be successfully applied to species identification and also helps the recognition of cryptic species. Another example is the *F. graminearum* clade where phylogenetic species recognition revealed the presence of nine phylogenetic species that were previously treated as one species (O'Donnell *et al*., 2004; O'Donnell *et al*., 2000).

1.3 Sub-specific ranks to characterise *Fusarium* species

Many sub-specific ranks are currently in use for the *Fusarium* species, such as forma specialis, including race and vegetative compatibility groups. Forma specialis (f. sp.) for short, and the plural formae speciales (ff. spp.) is the most commonly used sub-specific rank among *Fusarium* species and refers to the host preference of isolates that are morphologically indistinguishable. For example, *F.*

solani f. sp. *pisi* causes wilting of peas while *F. solani* f. sp. *phaseoli* attacks beans. It has to be noted that formae speciales have no nomenclatural standing and are not governed by the International Code of Botanical Nomenclature as pathogenicity is not a reliable ancestral trait (Greuter *et al.* 2000). Each f. sp. can also be further subdivided into physiological races and vegetative compatibility groups (VCGs).

Races refer to the host cultivar preference of a given *forma speciales* (f. sp.). A classical gene-for-gene interaction was proposed as the basis for the development of host cultivars resistant to *Fusarium* diseases (Takken and Rep, 2010). Vegetative compatibility between isolates refers to the fusion of hyphae that anastomose to form a stable heterokaryon (Puhalla, 1985). Isolates that can form a stable heterokaryon are compatible and therefore can be categorised in the same vegetative compatibility group (VCG). The VCG phenotype has a multigenic basis in *Fusarium* (approximately 10-15 *vic* loci) and can be used to identify a set of isolates that share common alleles at those loci (Leslie and Summerell, 2006). If the alleles of one (or more) *vic* loci differ, then the heterokaryon is unstable which leads to cell lysis after hyphal fusion (Leslie, 1993). In practice, complementary nitrate-reductase mutants are used to determine vegetative compatibility of *Fusarium* isolates while growing on nitrate-containing media (Puhalla, 1985).

1.4 *Fusarium* pathogens in the UK

There are several economically important plant diseases caused by members of the *Fusarium* genus in UK cropping-systems. Fusarium head blight (FHB) of wheat is caused by co-existing *F. graminearum, F. culmorum, F. avenaceum, F. poae,* and *F. langsethiae* species and is a re-emerging threat to British crop

production with an increase in disease incidence to 39% over the last 10 years in the UK (Brown *et al*., 2011; Nicholson *et al*., 2003; CropMonitor). Also, toxin producers like *F. culmorum* and *F. graminearum* have been more frequently isolated from wheat compared to toxin non-producing competitor species such as *Microdochium nivale* (formerly *Fusarium nivale*) (Gosman *et al*., 2007).

Potato is also affected by *Fusarium* pathogens in the UK. Dry rot of potato is caused by *F. coeruleum, F. avenaceum, F. culmorum* and *F. sambucinum* and affects at least 1% of British potato tubers (Peters *et al*., 2008). Additionally, asparagus can suffer from asparagus decline, a disease associated with *F. oxysporum* f. sp. *asparagi*, *F. proliferatum*, *F. solani* and *F. redolens* (Wong and Jeffries, 2006). Legume hosts, such as peas and beans, are suffering from foot-rot symptoms caused by *F. solani* (Clarkson, 1978).

Important *Allium* crops such as onion, shallot, garlic, and leek are all affected by *F. oxysporum*. Onion basal rot, caused by *F. oxysporum* f. sp. *cepae,* was first reported in 1980 in Essex, UK and since 2006, onion basal rot is an increasing problem to UK growers (A. Findlay, BOPA, pers. comm.). Ornamental crops such as daffodils can suffer from basal rot symptoms caused by *F. oxysporum* f. sp. *narcissi* in the UK (Hanks and Carder, 2003). Another recent emerging *Fusarium* disease is internal pepper fruit rot, which could cause up to 37% loss to crops in the UK (O'Neill, 2008).

1.5 Molecular identification of the *Fusarium* species

A community effort is being made to enable the accurate identification of *Fusarium* isolates based on sequence similarity to well-characterised *Fusarium*

species (Geiser *et al*., 2004). A multiple sequence database called Fusarium-ID contains information on more than 1800 isolates representing 76 *Fusarium* species (Park *et al*., 2011; O'Donnell *et al*., 2010). New isolates can be initially identified based on sequences for the translation elongation factor 1α (*TEF*) gene, as well as two genes encoding the largest and second largest subunits of RNA polymerase (*RPB1* and *RPB2*, respectively) sequences against the Fusarium-ID sequence database. These three genes are highly informative at the species level in *Fusarium*; non-orthologous copies of the genes have not been detected in the genus and conserved primers are available that can be used to amplify and sequence these genes in all fusaria described to date (O'Donnell *et al*., 1998a; O'Donnell *et al*., 2010). More precise identification of new *Fusarium* isolates may require phylogenetic analysis based on multiple markers, e.g. the query sequence may represent a novel species not represented in Fusarium-ID. Sequence data of several other markers such as phosphate permease genes (*PHO*), β-tubulin (*TUB*), calmodulin (*CAL*), UTP-ammonia ligase (*URA*), trichothecene 3-O-acetyltransferase (*TRI101*), a putative reductase (*RED*), histone 3 (*H3*), intergenic spacer (*IGS*), the small nuclear subunit of ribosomal rDNA (*18S-rDNA*), the large nuclear subunit of ribosomal rDNA (*28S-rDNA*), the small mitochondrial subunit of ribosomal rDNA (*mtSSU*), and mating type genes (*MAT1-1* and *MAT1-2*) are also available for a multi locus characterization of *Fusarium* pathogens and their populations (Park *et al*., 2011).

1.6 *Fusarium oxysporum* species complex

Fusarium oxysporum Schlecht., is the most common species of the genus, commonly occurs in the soil as a saprophyte but is also a well-known plant endophyte and an emerging pathogen of humans. It was recently identified as the 5th

most important plant pathogenic fungus based on its economic and scientific impact after *Magnaporthe oryzae*, *Botrytis cinerea*, *Puccinia* spp. and *Fusarium graminearum* (Dean *et al.*, 2012). One of the most devastating diseases caused by *F. oxysporum* is Panama disease of banana that almost completely destroyed the export trade in the 1960s (Ploetz, 2000). *F. oxysporum* can cause disease losses in almost all vegetable and ornamental crops as well as field crops such as cotton and a few palm species (Di Pietro *et al*., 2003).

F. oxysporum as a species was defined by Snyder and Hansen over 50 years ago but more recent work indicates this taxon is actually a genetically heterogeneous polytypic morphospecies (Kistler, 2001). No sexual stage has been identified for *F. oxysporum* and therefore it is regarded as a species complex; a complex of clonal lineages within the *Fusarium* genus. Despite the predominant asexual reproduction of *F. oxysporum,* mating type loci were identified and the associated *MAT* genes were found to be functioning correctly (Yun *et al*., 2000).

The *F. oxysporum* species complex comprises different formae speciales that collectively cause wilts of leaves and stem, root, bulb and crown rots as well as both pre- and post-emergence damping-off of over 100 different plant host species. It has been shown that four economically important formae speciales: *cubense, lycopersici, radicis-lycopersici* and *melonis* were found to be polyphyletic (*i.e.* several independent clonal lineages are present in each f. sp.) based on nuclear and mitochondrial gene genealogies (O'Donnell *et al.*, 1998a; Figure 1).

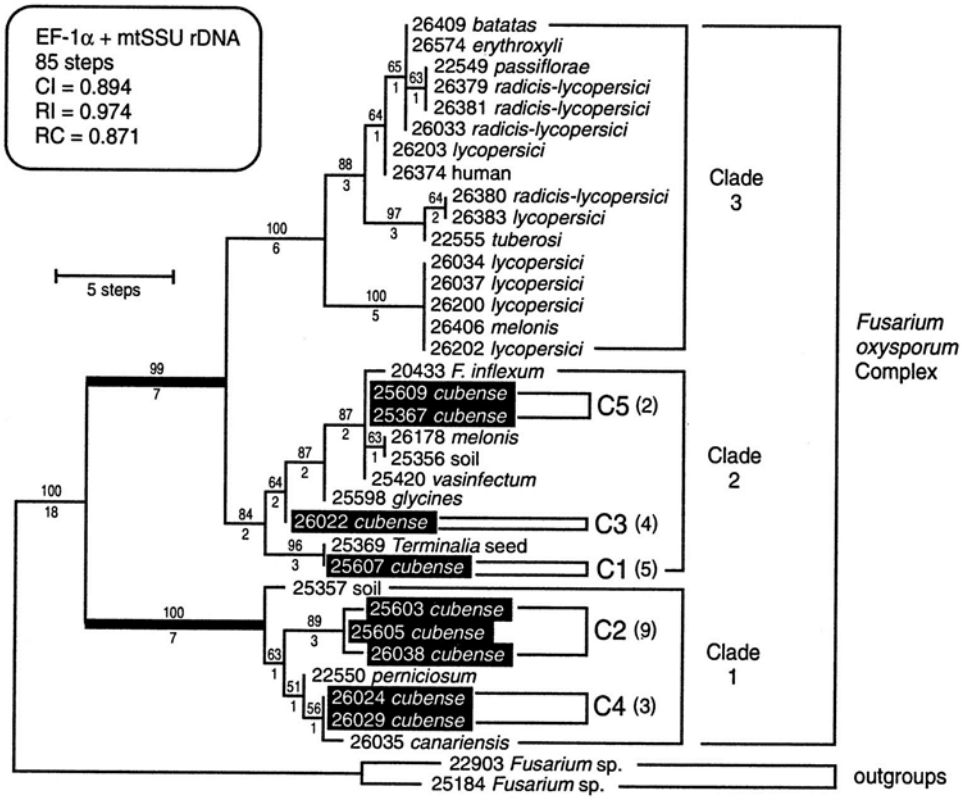

Figure 1. Single most-parsimonious phylogram by parsimony branch-and-bound search implemented in PAUP based on the combined translation elongation factor 1α (*TEF*) gene and mtSSU rDNA dataset for the *Fusarium oxysporum* complex rooted with sequences from *Fusarium* sp. NRRL 22903 and 25184. The five clonal lineages (C1-C5) of ‘‘*F. oxysporum* f. sp. *cubense*’’ are numbered according to the frequency with which each has been recovered from diseased bananas (after O’Donnell *et al*., 1998a).

Furthermore, amplified fragment length polymorphism (AFLP) markers were used in an extensive study by Baayen *et al.* (2000) to identify monophyletic and polyphyletic/paraphyletic formae speciales. This study also revealed that formae speciales comprising more than one VCG are not usually monophyletic (e.g. *lycopersici, gladioli, asparagi, lini,* and *dianthi*), but isolates originating from different host species can be grouped in the same clade. This finding suggests that pathogenic ability emerged convergently as no sexual stage has been observed in this fungus. Moreover, vegetative hyphal fusion (anastomosis) can only occur between

compatible *F. oxysporum* isolates (vegetative compatibility) which together results in the development of genetically isolated clonal lines. However, there are two studies published which provide some explanation: First, parasexual recombination between vegetatively incompatible strains has been observed *in vitro* which resulted in stable hybrids (Molnar *et al.*, 1990; Teunissen *et al*., 2002). Second, mobile pathogenicity chromosomes (MPCs) exist in *F. oxysporum* f. sp. *lycopersici* (FOL), the forma specialis affecting tomato, and the transfer of two of these MPCs between isolates of *F. oxysporum* converted a non-pathogenic isolate into a pathogenic one, suggesting that these chromosomes can spread among clonal lineages through horizontal gene transfer (Ma *et al*., 2010).

1.7 Disease cycle and infection process of *Fusarium oxysporum*

Fusarium oxysporum is a soil-borne pathogen of a broad range of agricultural and ornamental crops and also a common saprophyte on plant debris in soil. In soil it can survive as mycelium on decaying plant debris or as asexual micro- and macrospores or chlamydospores (Abawi and Lorbeer, 1972). Plants are infected by directed growth of *F. oxysporum* conidial germ tubes or mycelium which penetrates the root epidermis at the root tips or at natural wounds such as during the formation of lateral roots (Cooper and Bishop, 1983ab; Hutson and Smith, 1983). The infectious hypha infects the root through natural openings between epidermal root cells and grows through the root cortex intercellularly until it reaches the xylem's pits. In the xylem vessels, the mycelium branches produce chlamydospores, which are carried by the plant's sap stream (van der Does *et al*., 2008; Michielse and Rep, 2009). The colonisation of the xylem leads to the blockage of the xylem vessels and

/or toxin production and host defence responses, including production of pectic gels, gums and tyloses and vessel crushing by the proliferation of parenchyma cells (Beckman, 1987); and causing various symptoms such as wilting, chlorosis, necrosis, leaf drop, browning of the vascular system, and stunting.

Resistant tomato plants respond quicker to *Fusarium oxysporum* f. sp. *lycopersici* and contain the fungus by callose deposition and production of pectic gels, tyloses and gums in the infected xylem vessels instead of a classical hypersensitive response (HR) (i.e. cell death) than those that are susceptible (Mes *et al*., 2000).

F. oxysporum can spread short distances by irrigation water, contaminated agricultural machinery, via air or long distances by infected seeds and planting material (Abawi and Lorbeer, 1972).

1.8 Molecular mechanisms in the pathogenicity of *Fusarium oxysporum*

Several genes which are important in molecular mechanisms underpinning the pathogenicity and virulence of *F. oxysporum* have been identified during the last ten years. Forward and reverse genetic approaches have been applied to understand the importance of genes involved in signal transduction, utilisation of host nutrients, transcription and defence mechanisms.

1.8.1 Effectors

Effectors are “secreted proteins and other molecules which allow plant-associated organisms to modulate plant defence circuitry and enable colonization of plant tissue” (Hogenhout *et al*, 2009).

Plants have developed two lines of defence against pathogens. The first one provides defence against all pathogens and is based on the recognition of pathogen-associated molecular patterns (PAMPs or MAMPs for microbe-associated molecular patterns) such as chitin and β-glucan (main components of the fungal cell wall). This is termed PAMP-triggered immunity (PTI; Zipfel and Rathjen, 2008). Pathogens have developed ways to overcome basal defence using effectors, and as a response to this, plants developed a second line of defence to recognise these effectors. This is known as effector-triggered immunity (ETI; de Wit *et al*., 2009).

Small *in planta* secreted effectors called “secreted in xylem” (Six) proteins have been identified from FOL which interact (directly or indirectly) with tomato resistance genes (Takken and Rep, 2010). Several dominant plant resistance (*I*, for immunity) genes against different FOL races were identified (Huang and Lindhout, 1997): *I* and *I-1* genes confer resistance only to FOL race 1; *I*-2 is effective against FOL race 2 (which overcomes *I* and *I-1*); and I-3 confers resistance to FOL race 3 (and overcomes *I*, *I*-1 and *I*-2) (Rep *et al.*, 2005). Tomato plants carrying resistance (*I*, *I-1*, *I-2* and *I-3*) genes are able to recognise Six1, Six3 and Six4 proteins produced by the fungus, resulting in the tomato becoming resistant to the disease. The recognition of Six1, Six3 and Six4 proteins by the tomato leads to avirulence, and therefore the encoding genes are called avirulence genes (*AVR1- AVR3*; Rep *et al*., 2004).

Gene knockout experiments showed that Six4 (Avr1) is required for *I* and *I-1*-mediated disease resistance, whereas Six3 (Avr2) is needed for *I-2*-mediated resistance and Six1 (Avr3) is essential for both I-3-mediated and I-2-mediated resistance (Houterman *et al*., 2008; Houterman *et al*., 2009). The *SIX4* gene is only present in FOL race 1 strains while race 2 and race 3 isolates differ only in their *SIX3* gene sequences (Lievens *et al*, 2009a). Therefore it is likely that race 2 strains evolved through loss of *SIX4* (*AVR1*) from race 1 strains, while mutations in the *SIX3* (*AVR2*) led to the development of race 3 strains (Houterman *et al*., 2009).

Comparison of genome sequences of FOL, *F. graminearum*, and *F. verticillioides* revealed mobile pathogenicity chromosomes (MPCs) in FOL (Ma *et al*., 2010). Genomic regions were found in FOL that include four entire chromosomes (chromosomes 3, 6, 14 and 15) and parts of chromosome 1 and 2 which are rich in transposons and genes related to pathogenicity. Interestingly, *SIX4* (*AVR1*), *SIX3* (*AVR2*) and *SIX1* (*AVR3*) are located on chromosome 14 along with *SIX2, SIX5, SIX6* and *SIX7*. The transfer of chromosome 14 between isolates of *F. oxysporum* converted a non-pathogenic isolate into a pathogen (Ma *et al*, 2010).

To date only one resistance gene (*I-2*) has been cloned from the tomato which confers resistance to FOL race 2 strains (Simons *at al*., 1998). *I-2* locus is encoding a protein containing a nucleotide binding site motif and leucine-rich repeats (Simons *et al*., 1998). Expression studies revealed that *I-2* is abundant in the tissue surrounding the xylem vessels in the roots and stem of tomato plants (Mes *et al*., 2000). Avr2 recognition by I-2 can be artificially induced in leaves and stems, and is visible as a hypersensitive response (Houterman *et al*., 2009). Amino acid mutations (V41 → M, R45 → H or R46 → P) of Avr2 prevent recognition by I-2 in tomato, but do not interrupt its active site (Houterman *et al*., 2009). It is also known that Avr2 is

secreted into the xylem, but I-2 is present in the tomato cytosol (Houterman *et al*., 2009).

Thus far it has not been shown how Avr2 and I-2 and interact, although three possibilities were proposed by Takken and Rep (2010): (i) direct interaction of the two proteins, (ii) I-2 guards the target of Avr2 (guard model) or (iii) I-2 mimics the target of Avr2 (decoy model). No evidence has been found for the direct interaction of the proteins so far (Takken and Rep, 2010). Three proteins were found binding to Avr2 which were identified as chaperones and other proteins involved in protein maturation (van Bentem *et al*., 2005; Takken and Rep, 2010). Two additional proteins were identified from the tomato as interactors of *I-2*, which when stably silenced did not compromise *I-2*-mediated disease resistance (Lukasik-Shreepaathy *et al*., 2012).

The molecular basis of *Fusarium*-tomato interactions can be summarized as an example of zig-zag evolution of plant-pathogen interactions (Jones & Dangl, 2006; Takken and Rep, 2010). In phase 1, soil habitant *F. oxysporum* is recognized by tomato, but unable to invade plant, due to PTI. In phase 2, *F. oxysporum* deploys the combination of effectors, such as Avr2 and Avr3, enzymes and metabolites to overcome basal immunity. In phase 3, Avr2 and Avr3 directly or indirectly are recognised by nucleotide-binding and leucine-rich repeat (NB-LRR) proteins I-2 and I-3, respectively, that trigger ETI. In phase 4, FOL escaped recognition by point mutations in Avr2 and also by suppressing both I-2 and I-3 by Avr1. In phase 5, in tomato I-1 evolved to recognize Avr1 to prevent infection by FOL.

1.8.2 Transcription factors

Two transcription factors required for *F. oxysporum* pathogenicity (*FOW2* and *SGE1*) and two others (*FTF1* and *FOST12*) present only in highly virulent isolates have been identified (Michielse *et al.*, 2009b; Imazaki *et al*., 2007; Ramos *et al*., 2007; Asuncion *et al*., 2010). *SGE1* (*SIX* Gene Expression 1), a nuclear protein, is essential for pathogenic growth and the expression of *SIX* genes of FOL, but, it is not required for root colonisation and penetration (Michielse *et al*, 2009b). The only difference between the Sge1 mutant and wild type isolates, apart from pathogenicity, was reduced conidiation.

Another important regulator of pathogenic development is the Fow2 of *F. oxysporum* f. sp. *melonis* (the *F. oxysporum* gene required for wilt symptom 2), a Zn(II)2Cys6-type transcription regulator, that is required to invade roots and colonise melon tissue, but does not impair vegetative growth and conidiation (Imazaki *et al*., 2007).

A third transcription factor, *Fusarium* transcription factor 1 (*FTF1*), also has a Zn(II)2-Cys6 DNA-binding motif and plays a role in the establishment of the fungus within the plant and/or the progress of the disease (Ramos *et al*., 2007). *FTF1* is present as multiple copies in highly virulent *F. oxysporum* f. sp. *phaseoli* strains, while weakly virulent strains lack *FTF1*. Moreover, it is highly expressed during the first stages of common bean colonisation and the expression of *FTF1* correlates with the degree of virulence (de Vega-Bartol *et al*., 2011).

A fourth transcription factor (Fost12) of *F. oxysporum* f. sp. *phaseoli*, a homologue of Ste12 of *Saccharomyces cerevisiae*, is highly expressed during the period between 12 and 24 h after inoculation of common bean plants. Disruption mutants showed significant reduction in virulence and the transcriptional analyses of

FOST12 in several *F. oxysporum* f. sp. *phaseoli* strains during axenic growth suggest that Fost12 is a virulence factor required to deal with the nitrogen stress confronted by the pathogen during host plant colonisation (Asuncion *et al*., 2010).

1.8.3 Detoxification of antifungal compounds

In response to pathogen invasion, plants produce a great variety of soluble and cell-wall-bound phenolic compounds (such as ferulic, vanillin and coumaric acid) which can inhibit fungal growth and / or by their accumulation (lignification) reinforce the plant cell-wall (Niemann *et al*., 1991). In addition to this, some plants produce saponins (e.g. tomatine produced by tomato) or pterocarpans (e.g. pisatin produced by peas) to inhibit fungal infection. Several fungal species, including *F. oxysporum*, produce enzymes to degrade these antifungal compounds to overcome plant defence.

Tomatinase and tomatine hydrolase, have been discovered from FOL, *Verticillium albo-atrum*, and *Botrytis cinerea, F. solani* (Lairini and Ruiz-Rubio, 1998; Sandrock and VanEtten, 1998; Quidde *et al*., 1998; Roldan-Arjona *et al*., 1999). Five putative tomatinase genes present in the genome of FOL, and the disruption of one (*TOM1*) of them resulted in 25% loss in tomatinase activity and a delay in the progression of the disease symptoms (Pareja-Jaime *et al*., 2008). On the other hand, the overexpression of *TOM1* accelerated the spread of the symptoms.

Pisatin-demethylase is involved in the detoxification of pisatin produced by pea plants and was originally found in *Fusarium solani* f. sp. *pisi* (*Nectria haematococca*) (VanEtten *et al*., 1980). Recently, its functioning homologue (*FoPDA1*) was discovered in *Fusarium oxysporum* f. sp. *pisi*. The transformation of

the *FoPDA1* gene into *Fusarium oxysporum* f. sp. *lini* promoted pathogenicity towards peas (Coleman *et al*., 2011ab).

Phenolic compounds can be degraded either through the β-ketoadipate pathway or by laccases (Michielse *et al*., 2012; Canero and Roncero, 2008). The deletion of 3-carboxy-*cis,cis*-muconate lactonizing enzyme (*CMLE*) of FOL, an enzyme of the β-ketoadipate pathway, led to increased sensitivity to phenolic compounds and impaired root invasion and therefore loss of pathogenicity (Michielse *et al*., 2012). The molecular and functional characterisation of six putative laccase genes of FOL (*LCC1*- to *LCC5*, and *LCC9*) revealed that *LCC1, LCC3*, and *LCC9* are expressed during root and stem infection, although targeted inactivation of *LCC1, LCC3*, and *LCC5* did not have any effect on virulence (Canero and Roncero, 2008). Inactivation of a chloride channel coding gene (*CLC1*) caused a deficiency in laccase activity (probably by disabling the insertion of copper cofactor into maturing laccases) which was more severe than that found in any of the single laccase mutants (Canero and Roncero, 2008). This suggests that laccases may be collectively required for pathogenicity.

1.8.4 Enzymatic degradation of the plant cell wall

A plethora of plant cell wall degrading enzymes (CDWEs) have been predicted to play a role during infection of *F. oxysporum* as they are produced during host penetration and colonisation (Di Pietro *et al*., 2003). Individual inactivation of pectate lyases (*PL1*), xylanases (*XYL3, XYL4* and *XTL5*), proteases (*PRT1*) and polygalacturonases (*PG1, PG5* and *PGX4*) did not have an effect on the virulence of *F. oxysporum* (Di Pietro and Roncero, 1998; Huertas-Gonzalez *et al*., 1999ab; Garcia-Maceira *et al*., 2000; Garcia-Maceira *et al*., 2001; Di Pietro *et al*., 2001b;

Gomez-Gomez *et al*., 2001; Gomez-Gomez *et al*., 2002). Inactivation of a transcription factor (*XLNR*) that activates the expression of xylanases and cellulases reduced the xylanase activity, but did not have an effect on virulence (Calero-Nieto *et al*., 2007). Similarly, deletion of a transcription factor (*CTF1*) that activates cutinase and lipase genes was found to be dispensable for the virulence of *F. oxysporum* (Rocha *et al*., 2008). Cell-wall degrading enzymes are under carbon catabolite repression, which is controlled by a sucrose non-fermenting 1 gene (*SNF1*). The disruption of this gene reduced expression of several genes encoding cell wall-degrading enzymes and delayed infection of the host (Ospina-Giraldo *et al*., 2003). An F-box protein (*FRP1*) is involved in the expression of CDWEs, non-sugar carbon catabolism, host colonisation and therefore pathogenicity (Duyvesteijn *et al*., 2005; Jonkers *et al*., 2009; Jonkers *et al*., 2011).

These results suggests that enzymes involved in plant cell wall degradation are important virulence factors in *F. oxysporum*, although multiple copies of functionally redundant enzymes can mask the loss of individual CDWEs.

1.8.5 Signal transduction

Two conserved signal transduction cascades are present in *F. oxysporum*, a cyclic adenosine monophosphate-protein kinase A (cAMP-PKA) cascade and a mitogen-activated protein kinase (MAPK) cascade. These are required in order to recognise the host, attach to and penetrate the root epidermis, overcome the plant immune system, secrete toxins and small peptides and sporulate (Di Pietro *et al*., 2003).

FOL isolates were unable to attach to tomato roots and grow invasively in fruit tissue when MAPK (*FMK1*) was inactivated, although this mutant showed

normal growth (except becoming hydrophilic) and sporulation on artificial media. These mutants produced less polygalacturonase and pectate lyase compared to wild type which suggests that Fmk1 controls the expression of enzymes during early stages of infection (Di Pietro *et al.*, 2001a). Recently a mucin-type transmembrane sensor (Msb2) was discovered that promotes invasive growth and plant infection upstream of Fmk1 while contributing to cell integrity through a distinct pathway (Pérez-Nadales and Di Pietro, 2011).

Other proteins involved in the MAPK pathway are the heterotrimeric G-proteins (consisting of α-,β- and γ-subunits), which play a role in the regulation of hyphal growth, sporulation and virulence. The ortholog of the Gαi-protein coding gene in *F. oxysporum* f. sp. *cucumerinum*, *FGA1*, was disrupted which led to reduced conidiation, virulence and also cAMP level (Jain *et al*., 2002). This decrease in the cAMP level might suggest that Fga1 is involved in the activation of cAMP-PKA cascade (Jain *et al*., 2002). Another Gαi-protein coding gene in *F. oxysporum* f. sp. *cucumerinum*, *FGA2* was identified and the deletion of this gene led to complete loss of virulence and increased heat-tolerance, but did not have an effect on colony morphology (Jain *et al*., 2005). Disruption of the Gβ subunit in *F. oxysporum* f. sp. *cucumerinum* resulted in reduced virulence on cucumber and a decrease in conidiation and cAMP level (Jain *et al*., 2003). These results were confirmed by using a FOL strain and additional observations were made, e.g. *FGB1* mutants did not form hyphal branches in liquid media (Delgado-Jarana *et al*., 2005). Deletion mutants of cyclic AMP-dependent protein kinase A of *F. oxysporum* (FoCPKA) showed reduced growth, morphology, root attachment, penetration, and pathogenesis in *Arabidopsis thaliana* (Kim *et al.*, 2011). A striking finding is that MAPK (*FMK1*) is dispensable for virulence in immunocompromised mice (*Mus musculus*) and wax

moths (*Galleria mellonella*) (Di Pietro *et al*., 2001a; Ortoneda *et al*., 2004; Navarro-Velasco *et al.*, 2011). All these results imply that signal transduction has a key role during infection to respond to host defence mechanisms and to adapt to plant and animal hosts.

1.8.6 Response to ambient pH

An important environmental factor that influences fungal growth and development is ambient pH. In *F. oxysporum*, a pH responsive transcription factor (PacC) that binds the consensus 5'-GCCAAG-3' sequence was found essential for virulence in immunocompromised mice and wax moths, but not in tomatoes (Ortoneda *et al*., 2004; Navarro-Velasco *et al.*, 2011). Inactivation of PacC, which is an activator of genes expressed in alkaline conditions and a repressor of those expressed in acidic conditions, induced increased virulence towards tomatoes, while its over expression led to reduced virulence (Caracuel *et al*., 2003).

1.8.7 Fungal cell wall maintenance

Chitin synthesis has been shown to be crucial for pathogenicity and hence several chitin synthase gene knock-out mutants on *F. oxysporum* lost virulence (*CHV5b*) or had reduced virulence (*CHV5, CHV7, CHV2*) (Martin-Urdiroz *et al*., 2008; Madrid *et al*., 2003). Additional enzymes, such as β-1,3-glucanosyltransferases (Gas1) and GTPase (Rho1), play active roles in fungal cell wall biosynthesis. Rho is a small monomeric G protein that functions as an essential signalling component of the fungal cell wall–integrity pathway (Caracuel *et al*., 2005). Inactivation of Gas1

dramatically reduced virulence on the tomato, exhibited restricted colony growth on solid substrates and increased the expression of *CHSV* (Caracuel *et al*., 2005).

1.8.8 Response to nitrogen source

Fungi can utilise a wide range of nitrogen sources, but ammonia and glutamine are preferred, and when these are not available, for example during *in planta* growth, other secondary sources can be used (Marzluf, 1997). Utilisation of these sources is highly regulated and requires *de novo* synthesis of catabolic enzymes and permeases. A key component in nitrogen utilisation is the global nitrogen regulator, a transcription factor (Marzluf, 1997). Disruption of this nitrogen regulator in *F. oxysporum* (FNR1) eliminated the expression of nutrition genes normally induced during the early phase of infection (Divon *et al*., 2006). Fmk1 MAPK of *F. oxysporum* controls virulence functions such as invasive growth, vegetative hyphal fusion and host adhesion, which are strongly repressed in the presence of the preferred nitrogen source ammonium (López-Berges *et al*., 2010).

1.8.9 Additional genes involved in pathogenicity

A mitochondrial carrier protein (Fow1) was found to be specifically required for pathogenicity in *F. oxysporum* f. sp. *melonis*. Deletion mutants of *FOW1* showed normal growth and conidiation in culture, but they were unable to colonise plant tissue and therefore had reduced virulence (Inoue *et al*., 2002).

Disruption of argininosuccinate lyase (*ARG1*) of *F. oxysporum*, catalysing the last step for arginine biosynthesis, led to reduced virulence towards melon (Namiki *et*

al., 2001). Recently, peroxisomal function was found to be necessary for the pathogenesis of *F. oxysporum* (Michielse *et al*., 2009a). Peroxisomes, organelles in filamentous fungi, are involved in the β-oxidation of fatty acids, peroxide detoxification and plugging the septal pores after hyphal wounding. Deletion of two genes involved in the biogenesis of peroxisomes (*PEX12* and *PEX26*) caused loss of virulence and reduced growth on fatty acids (Michielse *et al*., 2009a).

Moreover, genes (*FOXG_08602*) similar to spherullin (involved in tissue desiccation or hydration), transcriptional regulators (*FOXG_03318*) and two proteins with unknown function (*FOXG_09487* and *FOXG_02054*) were proven to be important for the pathogenesis of FOL (Michielse *et al*., 2009a).

1.9 Characteristics of fungal effectors

Host specificity may be determined by effector genes, therefore can potentially be used for the detection and identification of plant pathogens. Known effector genes have at least one of the characteristics which are listed in this section. Therefore, potential effector genes can be identified based on these criteria. This section is predominantly focussed on fungal and oomycete effector genes. Characteristics of *F. oxysporum* effectors are discussed in Chapter 4.

1.9.1 Trigger or prevention of host defence responses

Some effectors trigger host defence responses, whilst others prevent them depending on the repertoire of resistance genes which are present in the host. There are few examples available where it is known which host proteins are targeted. Avr2 of *Cladosporium fulvum* inhibits the hypersensitive response by binding to the

extracellular tomato cysteine protease Rcr3 (Rooney *et al*., 2005). Another effector of *C. fulvum* is Avr4 which binds to plant chitinases to prevent fungal cell degradation (van den Burg *et al.*, 2006). Effectors not only exist in plant pathogens, but also in the mutualistic ectomycorrhizal basidiomycete *Laccaria bicolor* and in the arbuscular mycorrhizal fungus *Glomus intraradices* promoting symbiotic biotrophy (Martin and Nehls, 2009; Kloppholz *et al*., 2011).

1.9.2 Highly expressed during infection

Effectors are highly expressed specifically during plant colonisation and infection (Rep, 2005). Although, some avirulence genes such as *Avr9* (from the tomato pathogen *C. fulvum*), *CgDN3* (from *Colletotrichum gloeosporioides* affecting Brazilian lucerne) and *MPG1* (from the rice blast fungus *Magnaporthe grisea*) are also induced *in vitro* during nitrogen starvation (Snoeijers *et al*., 1999, Stephenson *et al.*, 2000; Talbot *et al*., 1993).

1.9.3 Short, cysteine rich and secreted into the host apoplast

Effectors are secreted during infection either into the host apoplast (extracellular space, including xylem) or into the cytoplasm (intracellular space) (Kamoun, 2009).

Apoplastic effectors are generally small (<350 amino acid) cysteine rich proteins with a type II secretion signal at the N-terminal. Avirulence genes *Avr2*, *Avr4* and *Avr9* of *C. fulvum* and *EPI* genes of *Phytophthora infestans* can be mentioned as examples (reviewed by Kamoun, 2009). For example, *SnTox1* is a

necrotrophic effector (host-selective toxin) identified in the wheat pathogen *Stagonospora nodorum* that encodes a 117 amino acid protein containing 16 cysteine residues (Liu *et al*., 2012). The cysteine residues are important because disulphide bonds can stabilize the effector protein, once they are secreted into the apoplast.

1.9.4 Secreted into the host cytoplasm

Cytoplasmic effectors in fungi are difficult to identify, because they typically lack shared characteristics. Many are only predicted based on having a secretion signal. However others have been described that lack a signal peptide, such as in the cereal pathogen *Blumeria graminis* f. sp. *hordei* (Ridout *et al*., 2006). Only 60% of the Crinkler effectors (CRNs) of the potato pathogen *P. infestans* possess a predicted signal peptide (Haas *et al*., 2009) and they are not particularly short (>400 amino acid). The Pwl effectors, generally found in rice pathogens, are small, glycine-rich secreted proteins which confer avirulence on weeping lovegrass and finger millet (Kang *et al*., 1995).

1.9.5 Possess specific enzymatic or unknown functions

Sequences of effectors indicate enzyme functions such as host cell wall degradation (Avr4 effector of *C. fulvum*) or proteases (Avr9 effector of *C. fulvum*) (van Esse *et al*., 2007, van den Hooven *et al*., 2001). A few of them show similarity to other known effectors *e.g*. SnTox1 of *S. nodorum* shows a high level of similarity to the PtrToxA gene from *Pyrenophora tritici-repentis* as they both encode toxins which interact with the same locus in wheat (Friesen *et al*., 2008). However, a larger

proportion of known effectors have novel sequences, for example in *Colletotrichum higginsianum* (Kleemann *et al*., 2012).

1.9.6 Contain certain motifs or domains

Motifs have been identified from some of the effectors. Most oomycete effectors contain a RXLR-dEER (RXLR-effectors) motif which has a role in the delivery of the effector to the host (Whisson *et al*., 2007). CRN effectors of *P. infestans* are defined by the presence of LFLAK and DWL domains which have roles in effector translocation into the host (Birch *et al*., 2008). Analysis of the genome of *Hyaloperonospora arabidopsidis* revealed the presence of 134 potential effector genes containing HaRxLs (Baxter *et al*., 2010). Avr4 (*C. fulvum*) orthologues are present in many fungal species such as the cereal pathogen *Septoria tritici* (*Mycosphaerella graminicola*), the rice blast fungus *M. oryzae* and the wilt pathogen *Verticillum dahliae*, which can be identified based on the presence of LysM domain in all of them (Marshall *et al*., 2011, Klosterman *et al*., 2011, Mentlak *et al*., 2012). The Y/F/WxC motif discovered in *B. graminis* f. sp. *hordei* has been proposed to define a new class of effectors from haustoria-producing pathogenic fungi (Godfrey *et al*., 2010).

1.9.7 Encoded in a close proximity of other pathogenicity related genes

Pathogenicity related genes are often encoded on regions and even on entire chromosomes in fungal species. For example, the avirulence genes *AbrLm1* and *AvrLm6* of *Leptosphaeria maculans* are encoded in a GC-low, gene-poor,

heterochromatin-like region surrounded by a GC-rich region containing long-terminal-repeat (LTR) retrotransposons (van de Wouw *et al*., 2010). Moreover, host specific toxin genes of the tomato pathogen *Alternaria arborescens* are located on conditionally dispensable chromosomes (Hu *et al*., 2012).

1.9.8 Accumulated or secreted through haustoria, appressoria and infectious hyphae

Effectors are often accumulated and secreted through structures enabling entry into host such as haustoria, appressoria, and infectious hyphae. Highly expressed effector genes were identified from the appressoria of the *Brassica* pathogen *C. higginsianum* or rice blast fungus *M. oryzae* (Kleemann *et al*., 2008, O'Connell *et al*., 2012; Mentlak *et al*., 2012) and in the haustoria of *Melampsora lini* (Dodds *et al*., 2004).

1.10 Identification of fungal effectors

In 1942, Harold Henry Flor proposed his pioneering theory of gene-for-gene relationships based on his observations on the flax – *Melampsora lini* pathosystem (Flor, 1971). He proposed that for every dominant avirulence gene (*Avr*) in the pathogen there is a matching dominant gene (*R*) determining resistance in the host plant. At this time, the identification of avirulence genes was not possible due to the lack of methods such as cosmid cloning. The first avirulence gene, *avrA* of *Pseudomonas syringae* pv. *glycinea* was cloned by Staskawicz *et al*. in 1984. In 1991, the first fungal avirulence gene, *avr9* of *Cladosporium fulvum* was cloned by van Kan and his colleagues (van Kan *et al*., 1991). The first resistance gene, *Hm1* in maize to *Cochliobolus carbonum,* was identified by Johal and Briggs in 1992.

Map based cloning was the first approach used to identify avirulence genes, but since then many new technical discoveries have been made enabling faster identification of these genes. For instance, biochemical analysis of FOL infected tomato xylem sap led to the identification of the Six proteins (Rep, 2005). Similarly, small secreted proteins were identified by mass spectrometry-based proteomics from the haustoria of the barley pathogen *Blumeria graminis* f. sp. *hordei* (Bindschedler *et al*., 2009). Reverse genetics approaches, restriction enzyme mediated integration (REMI) and *Agrobacterium*-mediated transformation (ATMT) have also been successfully used to identify pathogenicity related genes (Rogers *et al*., 2004; Inoue *et al*., 2002). *Agrobacterium*-mediated insertional mutagenesis was used to identify 111 pathogenicity related genes of FOL (Michielse *et al*., 2009).

Recent advances in sequencing technologies and bioinformatics have accelerated the identification of (candidate) effector genes (Alfano, 2009). *In silico*

tools, such as SIGNALP, enable the identification of signal peptide sequences (Nielsen *et al*., 1997) and the latest version of this software is even capable of discriminating signal peptides from transmembrane regions (Petersen *et al*., 2011). This tool has revolutionised the prediction of secreted effectors from haustoria- or appressoria-specific expressed sequence tag (EST) libraries and has been used on fungi such as *Uromyces fabae, Phytophthora infestans, M. lini, Magnaporthe grisea* and *Colletotrichum higginsianum* (Kemen *et al*., 2005, Tian *et al*., 2004, Catanzariti *et al*., 2006, Dean *et al*., 2005, Kleemann *et al*., 2008).

Another *in vitro* method for the identification of secreted proteins is 'yeast-based signal sequence trap' which was successfully applied to *Phytophthora sojae* and *Uromyces fabae* (Lee *et al*., 2006; Link and Voegele, 2008). An exciting new method is deep RNA sequencing which enabled the identification of a single effector Ave1 of *Verticillium dahliae* corresponding to the tomato immune receptor Ve1 (de Jonge *et al*., 2012). The increasing number of genome sequences provides an ample opportunity to predict secreted protein and effector genes related to plant-associated species. This has been done successfully for *P. sojae*, *P. ramorum*, *Hyaloperonospora arabidopsidis, Albugo candida* and *Fusarium graminearum* (Win *et al*., 2007, Fabro *et al*., 2011; Saunders *et al*, 2012; Brown *et al*., 2012; Link *et al*., 2011).

Candidate effectors can also be identified by comparative genomics, looking at differences in GC composition or codon usage and searching for secretion signals, motifs or sequences similar to other effectors or sequences with no known homologues in other species (Alfano, 2009). Blast2GO software can be used for the rapid and automated annotation of predicted proteins which gives information on the similarity to known sequences and also about the presence of a secretion signal

(Conesa *et al*., 2005). The PHI-BASE database comprises a list of 1065 experimentally confirmed pathogenicity related genes of 97 pathogens (Winnenburg *et al*., 2008). This database provides an enormous resource for the identification of homologues of known pathogenicity related genes in genome sequences (van de Wouw and Howlett, 2011). The number of bioinformatics tools and sources is increasing which enables the identification of an increasing number of candidate effectors, aiding the future identification of effector targets in host plants (Saunders *et al*., 2012).

1.11 OBJECTIVES AND OUTLINE OF THE THESIS

The primary objective of this study was to characterise the diversity and the species and sub-species level identity of *Fusarium* species populations associated with diseased *Allium* and sweet pepper crops in the UK. No survey or study of *Fusarium* causing problems on these hosts has previously been done and there is a clear need to identify and characterise the species responsible to inform disease management strategies. Rapid and reliable detection and identification of potential plant pathogens is required to inform correct control measures (Lievens *et al*., 2008). Molecular methods offer invaluable solutions to facilitate the rapid detection and identification of pathogens. These methods also enable cultivation independently of the detection of pathogens, especially obligate pathogens and soil borne diseases where mixed populations are present (e.g. coexisting saprotrophic and pathogenic isolates of the same species).

The secondary objective of this project was therefore to identify molecular markers suitable for the development of a sensitive PCR diagnostic assay for detecting pathogenic *F. oxysporum* on onion sets and distinguish these from non-pathogenic isolates.

The first part of the thesis is the General Introduction in which overview of *Fusarium* genus with special focus of *F. oxysporum* are described. This chapter is followed by experiments focusing on molecular identification of *Fusarium* isolates associated with diseased *Allium* species in the UK and testing and development of primer pairs used for *Fusarium* identification. The third chapter contains information on pathogenic variation of *Fusarium* species associated with diseased *Allium* crops and on the characterisation of *F. oxysporum* isolates based on a set of housekeeping genes, genotyping markers and an effector gene. This chapter is followed by the

description and discussion of preliminary results on genome sequencing of *F. oxysporum* f. sp. *cepae*. The fifth chapter discussed results on molecular identification of *Fusarium* isolates associated with internal fruit rot of sweet pepper in the UK. The final chapter contains the Conclusions, the findings from all chapters are put into a wider context and the contribution of this project to the state of knowledge and future prospective are discussed.

CHAPTER 2

IDENTIFICATION OF *FUSARIUM* PATHOGENS CAUSING DISEASES ON *ALLIUM* CROPS IN THE UK

2.1 INTRODUCTION

Onion (*Allium cepa* L.) is an important horticultural crop grown worldwide and is sold as dry bulb. Dry onion was one of the 20 most important agricultural commodities, based on value, in the UK in the last 15 years (FAOSTAT, 2010). Over 350,000 tonnes of marketed onions are produced annually on about 8700 hectares in the UK. The main production regions are Lincolnshire, Essex, Suffolk, Cambridgeshire, Bedfordshire, Yorkshire and Kent (O`Connor, 2005).

The most common fungal pathogens which cause losses for UK onion producers are *Botrytis aclada, Botrytis squamosa, Peronospora destructor, Sclerotium cepivorum, Urocystis cepulae* and *Fusarium oxysporum* f. sp. *cepae* (Maude *et al*., 1984; Clarkson *et al*., 2000; Gilles *et al*., 2004; Coventry *et al*., 2002; Taylor *et al*., 2012). *F. oxysporum* f. sp. *cepae* W. C. Snyder & H. N. Hansen (FOC) was described as the causal agent of onion basal rot, a soil-borne vascular disease. Onion basal rot causes economic losses of around £10–11 million annually in the UK, and is therefore a high priority in the research strategy of the British Onion Producers Association (Alaister Findlay, BOPA, pers. comm.). Onion basal rot is mainly a problem for individual growers on particular fields and losses of up to 60% can occur (Andrew Richardson, Allium and Brassica Centre, pers. comm.).

F. oxysporum f. sp. *cepae* (FOC) can cause symptoms at every stage of the plant development and infects the roots and basal plate of sets and bulbs, causing a brown basal rot that becomes covered with a white-pink mycelium (Figure 2A). Leaf tips yellow, leaves wilt beginning with the older outer leaves and the plants die (Figure 2B). FOC can also cause seedling damping off, or delayed emergence of seedlings (Cramer, 2000).

Figure 2. Onion basal rot symptoms **A** Development of mycelium on basal plate and **B** wilting and yellowing.

FOC invades the roots or the stem plate of onion bulbs by direct penetration or through wounds, and then grows through intercellular spaces until invading the xylem vessels and xylem parenchyma. Xylem vessels blocked by tyloses are observed in both roots and, more commonly, in the stem plate. The pathogen can break through the stem area and grow in the fleshy leaf base tissues and between the leaves. Chlamydospores are formed in the root cortex and in and around the xylem vessels, while microconidia are produced by hyphae growing between the scale tissues in the bulb (Abawi and Lorbeer, 1971).

The pathogen can spread in stores through the wounds of dormant bulbs (Özer & Köycü, 2004) and within and between fields on equipment and infected plant material (Maude, 2006; Cramer, 2000). The pathogen can survive as chlamydospores (thick-walled survival structures) for up to 10 years in the soil or on soil debris as saprotrophic mycelium where onions are grown continuously (Entwistle, 1990). The disease is more serious when soil temperatures exceed 25°C and soil moisture is high.

FOC isolates show different levels of aggressiveness in onion seedlings, but separate races have not been identified (Cramer, 2000). FOC comprises seven known vegetative compatibility groups (VCGs 0420 to 0426) and several single-member VCGs (SMVs). However, it should be noted that the VCG analysis was carried out only on isolates collected in Japan, South Africa, Colorado (United States), and Turkey (Southwood *et al.*, 2012).

Recent studies from the Netherlands, Uruguay, Serbia, Turkey and Washington State, USA reported a complex of *F. oxysporum* and *F. proliferatum* (teleomorph: *Gibberella intermedia*) species causing onion basal rot. Additionally, in Turkey *F. solani* (teleomorph: *Nectria haematococca*), *F. acuminatum* (teleomorph: *G. acuminata*) and *F. redolens* were also found to be very aggressive in onion (Galvan *et al*., 2008; du Toit *et al*., 2003; Klokocar-Smit *et al*., 2008; Bayraktar *et al*., 2011). In the Netherlands *F. avenaceum* (teleomorph: *G. avenacea*) was identified as weakly pathogenic (de Visser *et al*., 2005). In an early study, *F. equiseti* (teleomorph: *G. intricans*), *F. verticillioides* (teleomorph: *G. moniliformis*) and *F. tricinctum* (teleomorph: *G. tricincta*) were also all found to be pathogenic to onion (Mannerucci *et al*., 1987).

Basal rot symptoms caused by FOC can occur on onion (*A. cepa*), shallot (*A. cepa* var. *ascalonicum*), Welsh onion (*A. fistulosum*), chive (*A. schoenoprasum*) leek (*A. ampeloprasum* var. *porrum*) and garlic (*A. sativum*) (Bayraktar *et al*., 2010; Coskuntuna & Özer, 2008; Özer & Köycü, 2004; Swift *et al*., 2002; Figure 3). From diseased garlic *F. proliferatum, F. verticillioides, F. culmorum* and from diseased Welsh onion *F. redolens, F. verticillioides, F. solani* have also been isolated (Dugan *et al*., 2007; Dissanayake *et al*., 2009ab; Seefelder *et al*., 2002; Stankovic *et al*., 2007; Shinmura, 2002; Palmero *et al*., 2012).

Leeks can suffer from foot and or basal rot depending on which *Fusarium* species has infected the plant. Foot rot is caused by *F. oxysporum* and *F. avenaceum* (Figure 3), while basal rot is caused by *F. culmorum* (Armengol *et al*., 2001; Koike *et al*., 2003; Gilardi *et al*., 2009; Oxspring *et al*., 2004).

Members of the wild *Allium* flora have not been reported as potential hosts of *F. oxysporum* in the UK. The wild species *A. roylei, A. galanthum,* and *A. pskemense* showed an intermediate level of resistance against *F. oxysporum* and *F. proliferatum* (Galvan *et al*., 2008). There is some information suggesting that FOC can colonize without causing symptoms economically important weed species such as oxalis (*Oxalis corniculata*) and fat-hen (*Chenopodium album*) (Abawi and Lorbeer, 1972).

As with many other soil-borne diseases, onion basal rot is difficult to control. Chemical control is rather limited in the UK, partly because thiram (dimethylcarbamothioylsulfanyl-N,N-dimethylcarbamodithioate) is the only recommended fungicide in the UK, and this can only be used for seed-treatment (Health and Safety Executive, HSE). The other reason is the increasing demand for organic products and more sustainable approaches to disease control. Biocontrol agents such as *Trichoderma* species, *Bacillus subtilis* and *Pseudomonas fluorescens*

were shown to be effective against onion basal rot (Coskuntuna and Özer, 2008; Cramer, 2000), but only *B. subtilis* (sold as Serenade ASO) is registered for onion treatment in the UK (Fungicide Resistance Action Group, FRAG). Work is in progress to optimise field-scale control of Fusarium basal rot and white rot of onion using *Trichoderma* amended substrates and pellets, and onion residues (Ralph Noble, East Malling Research, pers. comm.). Good management practices can help to prevent the occurance and spread of onion basal rot such as use of at least a 4-year-crop rotation, cleaning agricultural machinery between fields, temperature and humidity controlled-storage and soil solarisation (Klein *et al*., 2011). It is not clear why onion basal rot has become an increasing problem in the UK since 2006, but theories include the role of recent erratic weather, withdrawal of fungicides and emergence of new and/or more aggressive isolates or a combination of the above (A. Richardson, A&B Centre, pers. comm., A. Findlay, BOPA, pers. comm.).

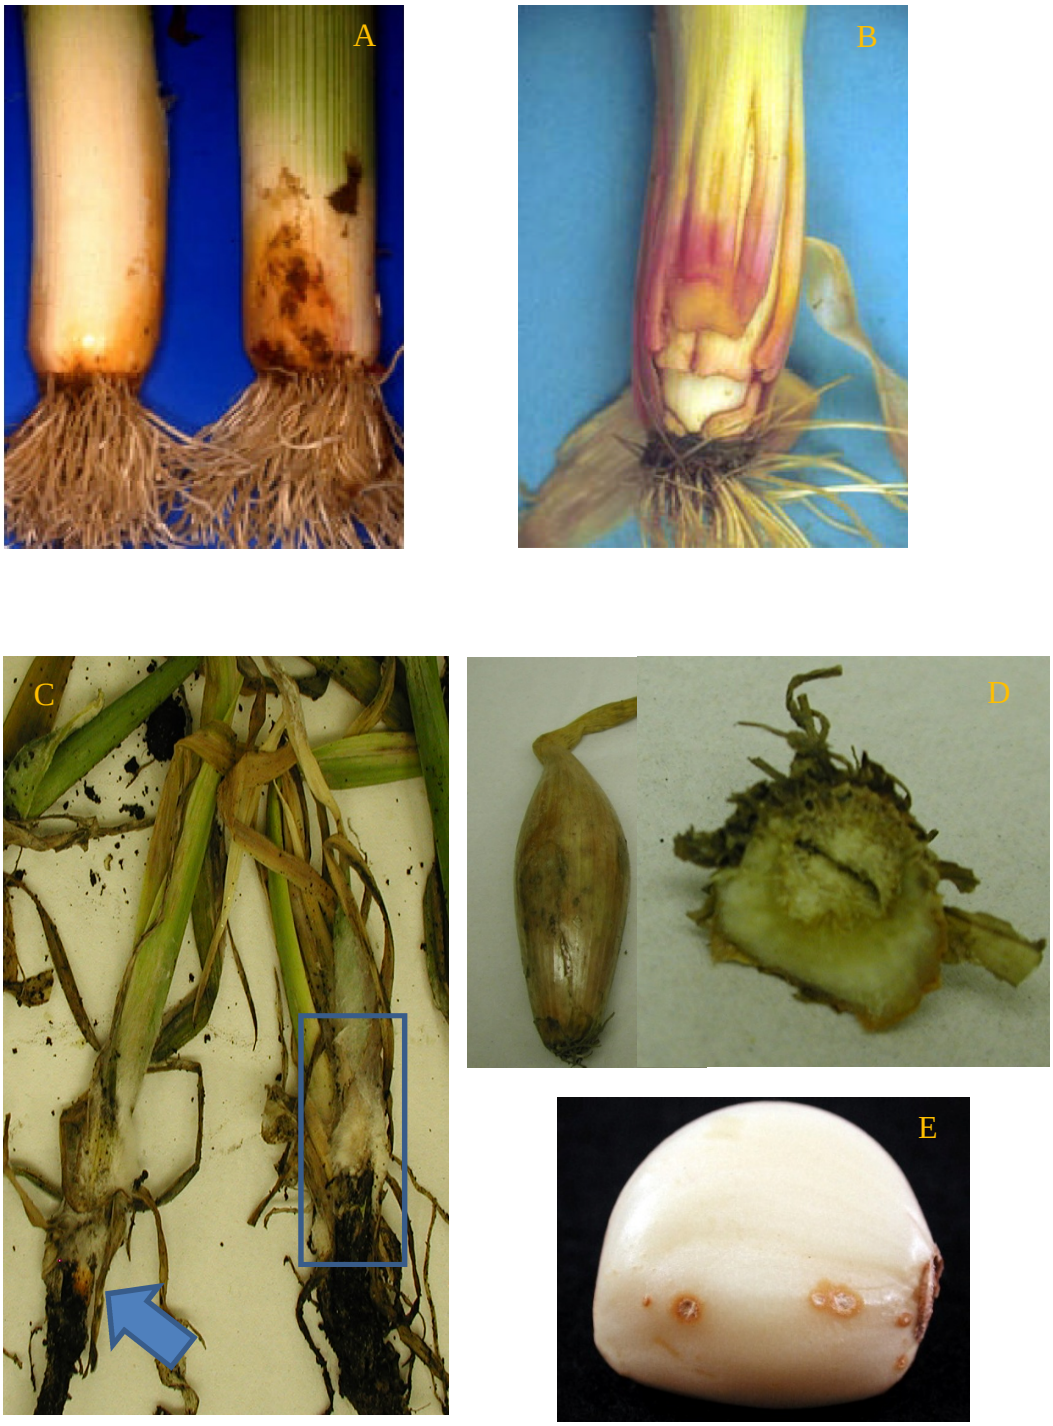

Figure 3. Fusarium rot symptoms of various *Allium* species. **A-B** Foot rot of leek (Photo credit: Hitch, C. J., SARDI) **A** *Fusarium avenaceum* causes a brown rot at the base of the shank. **B** *F. oxysporum* causes a pink discoloration on the shank. **C** Basal rot of leek, *F. culmorum* causes an orange discoloration on the shank and mycelial growth on leaves. **D** Basal rot of shallot **E** Basal rot of garlic (Photo credit: Putnam, M., Oregon State University).

2.2 AIMS AND OBJECTIVES

The overall aim of this chapter was to identify the species and sub-species of *Fusarium* populations on *Allium* crops in the UK and characterise their diversity.

Specific objectives were:

- To obtain *Fusarium* isolates from soil and *Allium* crops with basal rot symptoms
- To identify and characterise *Fusarium* species using genus- and species-specific primers and amplifying a common fungal housekeeping gene (*TEF*).

2.3 MATERIALS AND METHODS

2.3.1 Testing and development of primer pairs used for *Fusarium* identification

2.3.1.1 DNA extraction

DNA was extracted from 22 type cultures including *F. avenaceum, F. begoniae, F. cerealis, F. coeruleum, F. culmorum, F. equiseti, F. foetens, F. fujikuroi, F. graminearum, F. lateritium, F. oxysporum* f. sp. *tulipae, F. poae, F. proliferatum, F. redolens, F. sambucinum, F. solani, F. succisae, F. torulosum, F. tricinctum, F. verticillioides, Colletotrichum gloeosporioides* and *Microdochium nivale* (Appendix I) using a GenElute Plant Genomic DNA Kit (Sigma-Aldrich) following the producers protocol.

2.3.1.2 Polymerase chain reactions (PCRs) amplifying part of the *TEF* gene and ITS region for the confirmation of species level identity of *Fusarium* type cultures

Species level identity of the 20 type *Fusarium* cultures was confirmed by amplification and sequencing of the partial translation elongation factor 1α (*TEF*) gene, commonly used for fungal identification studies, using EF1 and EF2 primer pair and the cycling conditions published by O'Donnell *et al*. (1998a). Two closely related species, *C. gloeosporioides* and *M. nivale*, were identified based on ITS region using ITS1 and ITS4 primers and thermocycler conditions published by White *et al*. (1990). PCR reactions were carried out in a total volume of 20 µl which consisted of: 10 µl of RedTaq (Sigma-Aldrich*),* 7 µl of sterile water, 1 µl each of 20 µM forward/reverse primers and 1 µl DNA template (30 ng/µl).

PCR products were electrophoresed on 1.0 w/v % agarose gels in TAE buffer with 1 µl of GelRed (Biotium) per ml following standard procedures (Sambrook *et al*., 1989).

Sequencing reactions were carried out in a total volume of 10 µl which consisted of: 2 µl of Big Dye terminator 3.1 (Applied Biosystems, ABI), 2 µl of 5x sequencing buffer (ABI), 4 µl of sterile water, 1 µl of 4 µM forward/reverse primer and 1 µl PCR amplicon (200 bp PCR product: 30 ng/µl; 200-1000 bp product: 10 ng/µl) using an ABI Prism 3100 Genetic Analyser. Thermal cycling conditions were as follows: initial denaturation for 1 minute at 96°C, followed by 25 cycles of 10 seconds denaturation at 96°C, annealing for 5 seconds at the 50°C and extension for 3 minutes at 60°C. The program ended with a 4 minutes final extension at 60°C.

Basic editing of sequence files and preparation of consensus sequences was done using DNASTAR Lasergene 8.0. Sequences were compared with those deposited of National Center for Biotechnology Information (NCBI) by using the Basic Local Alignment Search Tool (BLAST; Altschul *et al*., 1990).

2.3.1.3 Testing of published primers pairs for *Fusarium* genus and species identification

For the rapid identification of fungal isolates recovered from *Allium* species and soil associated with basal rot, *Fusarium* genus and species-specific primer pairs were used. Compared to sequence based identification the use of specific PCR reactions is cheaper and faster. *F. oxysporum* and *F. proliferatum* have been recovered most frequently in association with onion basal rot in several countries (Galvan *et al*., 2008, du Toit *et al*., 2003, Klokocar-Smit *et al*., 2008, Bayraktar *et al*., 2011) and therefore specific primer pairs designed for the detection of these species were also tested. In total, two *Fusarium* genus-specific (Bluhm *et al*., 2004;

Abd-Elsalam *et al*., 2003), a *F. oxysporum*-specific (Mule *et al*., 2004) and a *F. proliferatum*-specific (Mule *et al*., 2004) primer pairs were initially tested on *F. redolens, F. culmorum, F. proliferatum, F. solani, F. oxysporum* f. sp. *tulipae*, *F. avenaceum, F. equiseti,* and *M. nivale* (see 2.3.1.1; Table 1). The published *Fusarium* genus-specific primers targeted the ITS region, while species specific primer pairs were designed based on calmodulin coding sequences (Bluhm *et al*., 2004; Abd-Elsalam *et al*., 2003; Mule *et al*., 2004).

PCR reactions were carried out in a total volume of 20 µl which consisted of: 10 µl of RedTaq (Sigma-Aldrich), 7 µl of sterile water, 1 µl each of 20 µM forward/reverse primers and 1 µl DNA template (30 ng/µl). Thermocycling conditions were as published (Bluhm *et al*., 2004; Abd-Elsalam *et al*., 2003; Mule *et al*., 2004).

Table 1. Sequences, target gene, specificity and origin of primers used for the identification of fungal isolates.

Primer name	Primer sequence (5`→3`)	Target	Specificity	Reference
ITS-Fu-f	CAACTCCCAAACCCCTGTGA	ITS region	*Fusarium* genus	Abd-Elsalam *et al*., 2003

CLPRO2	GCGAGACCGCCACTAGAT			

2.3.1.4 Development of novel a primer pair for the identification of isolates belonging to the *Fusarium* genus

A *Fusarium* genus-specific primer pair (exTEFfor and FUexTEFrev) targeting the *TEF* gene was designed to speed up the process of identification as *TEF* is the most widely used marker for *Fusarium* species identification. The *Fusarium* genus-specific primer pair was designed manually based on the *TEF* gene sequences of twelve fungal genomes (*F. graminearum. F. oxysporum, F. verticillioides, F. solani, Trichoderma reesei, T. atroviridae, T. virens, Epichloë festucae, Glomerella graminicola, Verticillium dahliae, Aspergillus nidulans,* and *A. terreus*) (BROAD, JGI). Self- and cross-hybridisation ability was tested by Oligo Analysis Tool (Eurofins). Primer specificity was tested *in silico* using NCBI BLAST tool (Altschul *et al*., 1990). All primers were synthesised by Invitrogen (Paisley, UK).

Specificity of exTEFfor and FUexTEFrev primers was tested on the 22 type cultures as listed in Section 2.3.1.1 using the same PCR reaction as in Section 2.3.1.2. Thermocycling conditions were as follows: initial denaturation for 5 minute at 94°C, followed by 35 cycles of 45 seconds denaturation at 94°C, annealing for 30 seconds at the 64°C and extension for 2 minutes at 72°C. The program ended with a 10 minutes final extension at 72°C. Species level identity of all *Fusarium* isolates was confirmed by sequencing the *TEF* gene using EF1 and EF2 primers (O'Donnell *et al*., 1998a) as in Section 2.3.1.2.

2.3.2 Sampling and isolation of *Fusarium* species associated with *Allium* species in the UK

Onion bulbs showing basal rot symptoms were collected from stores or directly from fields. Field samples were taken by walking diagonally across each field and taking bulb samples with symptoms of basal rot from at least ten plants per a field (Table 2). Approximately 1 cm^3 sections of diseased and healthy basal tissue of *Allium* samples (Table 2) were surface sterilised (twice in 70% ethanol for 5 minutes each followed by two rinses in sterile distilled water) and transferred onto water agar (20 g agar in 1L of distilled water) amended with antibiotics (1 g streptomycin sulphate and 0.12 g neomycin per L media to inhibit bacterial growth) and incubated at 25°C for 3 days. Isolates were sub-cultured onto potato dextrose agar (PDA, Merck) via hyphal tip transfer to obtain pure cultures. After 7-10 days incubation, isolates with different colony morphologies characteristic of *Fusarium* were selected for further studies.

Fusarium isolates (168) were recovered from onion bulbs showing basal rot symptoms from 17 samples collected in the UK (Table 2). Imported onion bulbs and sets were also used for isolations (35 isolates) to investigate the possibility of new *Fusarium* isolates being introduced into the UK from other countries (Table 2). These were imported originating from the Netherlands, Belgium and France, while imported onion bulbs were from Spain, the Netherlands, Chile and New Zealand. Garlic, shallot and leek plants were collected from production and processing sites in the UK in order to define which *Fusarium* species were present on other *Allium* crops (Table 2). Nineteen isolates were obtained from these.

Additionally, *Fusarium* isolates (77) were also obtained following isolations from soil samples from three field sites (Table 2, Figure 4). Soil samples (Table 2)

were air dried and sieved before plating on peptone PCNB agar (PPA) and Komada`s media (Nash & Snyder, 1962; Komada, 1975). To obtain individual *Fusarium* colonies, 1 $x10^{-2}$ and 1 $x10^{-3}$ dilutions were used (starting with 1 g of soil in 10 ml sterile distilled water). After 10 days isolates were sub-cultured onto PDA.

A field in Warwickshire (Table 2, sample reference 17) was chosen for sampling as the onions recovered showed basal rot symptoms (Figure 4A). Five soil samples (1 – 5) were collected from this field. A second field (Table 2, sample reference 6) in Suffolk showed severe basal problems at the half of the field (Figure 4B). Five soil samples were collected from both symptomless (1 - 5) and diseased (6 - 10) bulbs. A third field in Essex (Table 2, sample reference 8) was sampled three years after onions were grown and also a year before the next onion crop was due to be grown (Figure 4C). The cropping history of the field was well documented; onion was grown in 4-year-rotation with winter wheat and sugar beet. Five samples (11 – 15) were collected. The same onion field in Essex (Table 2, sample reference 8) was sampled intensively shortly before harvesting in September 2010. To study the spatial variation of *Fusarium* species in these fields, a total of 70 bulbs were taken from positions approximately 10 m apart by walking diagonally and transversally across the field. The area sampled had a long history of onion basal rot and the first incidence of the disease in the 1980's was reported in the same region and by the same grower. A four-year crop rotation was used to grow onions on this field in alternation with winter wheat and sugar beet.

All *Fusarium* isolates were stored on Spezieller Nährstoffarmer Agar (SNA, Nirenberg, 1976) at 4°C or as spore suspension in 15% glycerol-water solution at -80°C.

Table 2. Origin, date of collection, source, host, sample material and number of isolates obtained of samples collected for isolation of *Fusarium* species.

Reference number	Location of onion field	Date of collection	Source	Host	Sample material	No. of isolates

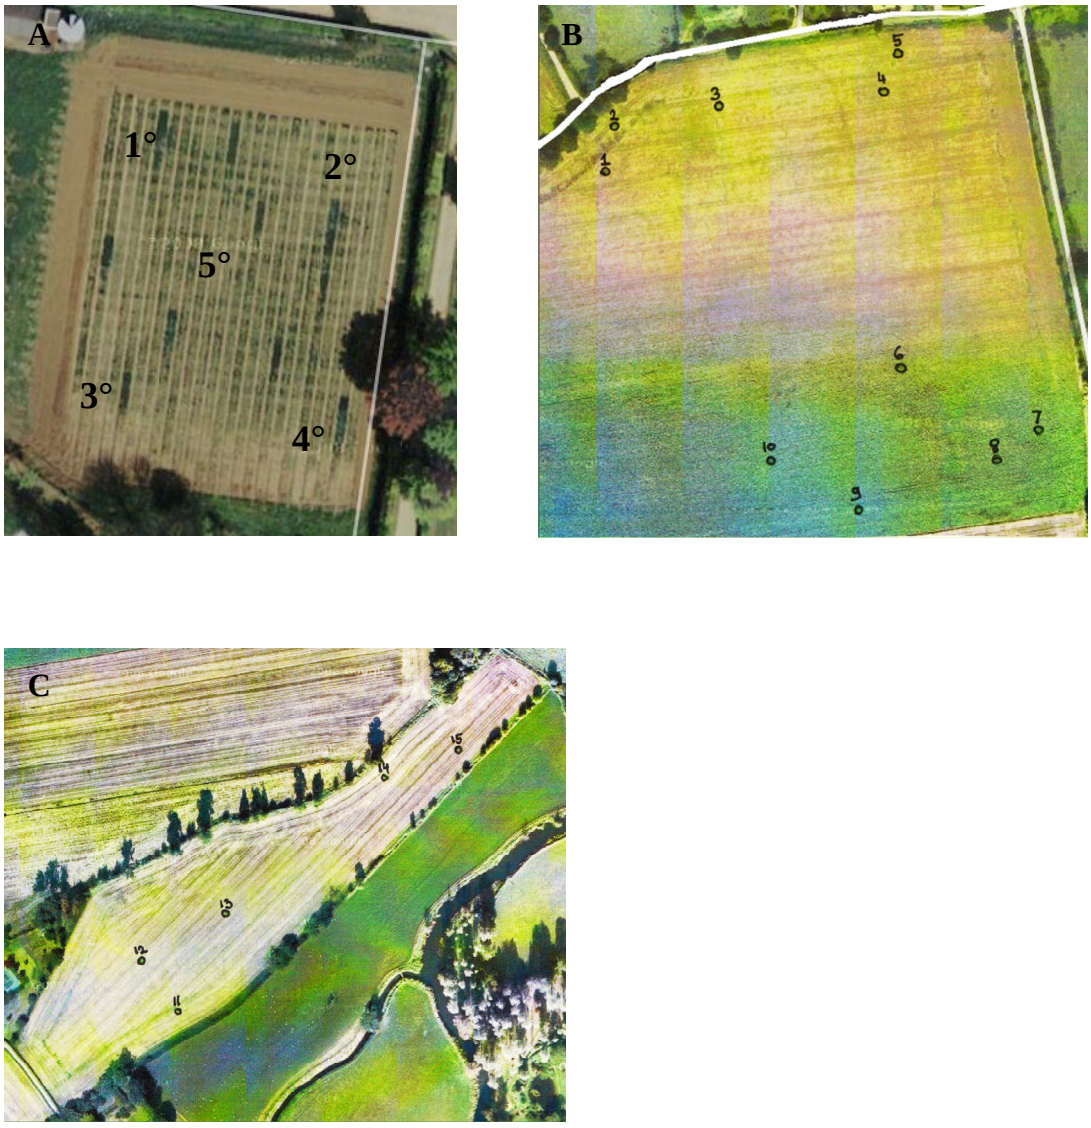

Figure 4. Soil sampling points (marked with circles) of three onion fields with onion basal rot incidence. **A** Five soil samples (1 - 5) were collected from field in Warwickshire with severe basal rot incident (reference number 17); **B** Field in Suffolk (reference number 6), onions showing onion basal rot symptoms were found only from half of the field (shaded in green). Five samples were collected from symptomless half (1 – 5) on the field and five samples (6 – 10) were collected from diseased half of the field; and **C** Five samples (11 - 15) were a field in Essex (reference number 8) with onion basal rot history.

2.3.3 Molecular identification of *Fusarium* isolates associated with *Allium* species

2.3.3.1 DNA extraction method used for the preliminary identification of *Fusarium* isolates

For preliminary identification of isolates, DNA was extracted by a method using 10% Chelex 100 solution adapted from Richlen and Barber (2005) and Talhinhas *et al*. (2009). Chelex 100 is an ion chelator which protects DNA molecules, removes magnesium from the sample and inactivates nucleases. The protocol involved the preparation of sterile 1.5 ml Eppendorf tubes containing 10% Chelex 100 (0.1 g Chelex 100 and 900 µl dH_2O). A loopful of mycelium was collected from 10-day-old cultures grown on PDA plate with a sterile cocktail stick. Mycelium was transferred into 1.5 ml Eppendorf tubes containing 10% Chelex 100 and vortexed for 30 seconds followed by 30 seconds centrifugation at 14000 rpm. Tubes were incubated at 95˚C for 20 minutes, then vortexed for 10 seconds followed by 10 seconds centrifugation for at 14000 rpm. DNA-containing supernatant was transferred into a sterile Eppendorf tube and stored at -20°C.

2.3.3.2 Molecular identification of *Fusarium* isolates associated with *Allium* species

Preliminary identification of isolates obtained from *Allium* species and soil (Table 2) employed *Fusarium* genus- and species-specific primer pairs (exTEFfor, FUexTEFrev, CLOX1, CLOX2, CLPRO1 and CLPRO2 primers) using published conditions as in Sections 2.3.1.3 and 2.3.1.4. Species-level identity of 234 isolates (Appendix II and Appendix III) obtained from *Allium* species and soil was confirmed by sequencing part of the *TEF* gene as in Section 2.3.1.4.

2.3.3.3 Cladistic analysis of *Fusarium* isolates associated with *Allium* species

TEF sequences from *Fusarium* isolates were aligned by Clustal W (Thompson *et al*., 1994) and cladistic analysis carried out based on neighbour-joining (Saitou & Nei, 1987), maximum parsimony and UPGMA (Sneath and Sokal, 1973) using MEGA 4.0 (Tamura *et al*., 2007). Bootstrap consensus trees were inferred from 1000 replicates and are taken to represent the evolutionary history of the taxa (Felsenstein, 1985). Branches corresponding to partitions reproduced in less than 50% bootstrap replicates were collapsed. Distances were computed using the Kimura 2-parameter model (Kimura, 1980). All positions containing gaps and missing data were eliminated from the dataset (complete deletion option). Published *TEF* sequences of *F. oxysporum* f. sp. *cepae*, *F. proliferatum*, *F. avenaceum* and *F. culmorum* were used as references (Table 3; Mbofung *et al*., 2007; Galvan *et al*., 2008; O'Donnell *et al*., 2009).

Table 3. Genbank accession numbers of translation elongation factor 1α (*TEF*) sequences, origin, year of collection, reference and distribution of *Fusarium* species pathogenic towards *Allium* spp. used for taxonomic reference.

2.4 RESULTS

2.4.1 Testing and development of primer pairs used for *Fusarium* identification

The specificity of published *Fusarium* genus- and species-specific primer pairs was tested on eight *Fusarium* cultures representing commonly found species in the UK and *M. nivale,* a species closely related to *Fusarium* genus, was used as a negative control.

The *Fusarium*-specific primer pair FuITS (Bluhm *et al*., 2004) were more reliable when used with *F. redolens* and *F. avenaceum* compared to the ITSFu pair which resulted in very faint bands (Abd-Elsalam *et al*., 2003; Table 4).

F. oxysporum specific PCR primers (Mule *et al*., 2004) were potentially suitable for distinguishing *F. oxysporum* from other *Fusarium* species, but needed to be used carefully as some of the other species also yielded PCR products with these primers but with different banding patterns (Table 4). The *F. proliferatum* specific PCR primers (Mule *et al*., 2004) were suitable for identifying isolates of this species as it gave a single bright band with *F. proliferatum* but not with any other species (Table 4).

The newly developed *Fusarium* genus-specific primer pair, exTEFfor ACCCGGTTCAAGCATCCGATCTGCGA and FUexTEFrev AGCTTGCCR GACTTGATCTCACGCTC was designed based on the *TEF* gene sequences of eight fungal genomes representing closely related genera (*Trichoderma, Epichloë, Glomerella, Verticillium* and *Aspergillus*). FUexTEFrev primer was found to be specific exclusively to *Fusarium* genus *in silico* when its specificity tested on the whole genome sequences of eight closely related fungal species. This novel primer pair was tested on 20 *Fusarium* species representing major plant pathogens and on

closely related *C. gloeosporioides* and *M. nivale* species. ExTEFfor and FUexTEFrev primers were able to amplify ~1269 bp product from all *Fusarium* species but not the two related species, *C. gloeosporioides* and *M. nivale* species (Figure 5).

In summary, two *Fusarium* genus-specific (both targeting the ITS region), a *F. oxysporum*-specific and a *F. proliferatum*-specific primer pair (both targeting calmodulin gene) were tested on a small set of isolates. Only one of the genus-specific (designed by Bluhm *et al*., 2004) and the two species-specific (published by Mule *et al*., 2004) primer pairs gave reliable results. A novel primer pair (exTEFfor and FuexTEFrev) targeting *TEF* gene was developed and tested successfully to identify/detect *Fusarium* species associated with onion basal rot.

Table 4. Primer efficiency in *Fusarium* genus-, *F. oxysporum*- and *F. proliferatum*-specific PCR screening.

Species	Isolate	FU-ITS[1]	ITS-FU[2]	CLOX[3]	CLPRO[3]
F. redolens	A18-2-5	+++	–	–	–
F. culmorum	C14-2-5	+++	+++	M	–
F. proliferatum	IMI 312182	+++	+	–	+++
F. solani	R161AF4	+++	+++	–	–
F. oxysporum	Fus 1	+++	+++	+++	–
F. avenaceum	2308-1b	+++	+++	–	–
F. equiseti	C-3-1-2	+++	+	M	–
M. nivale	08251	–	–	–	–

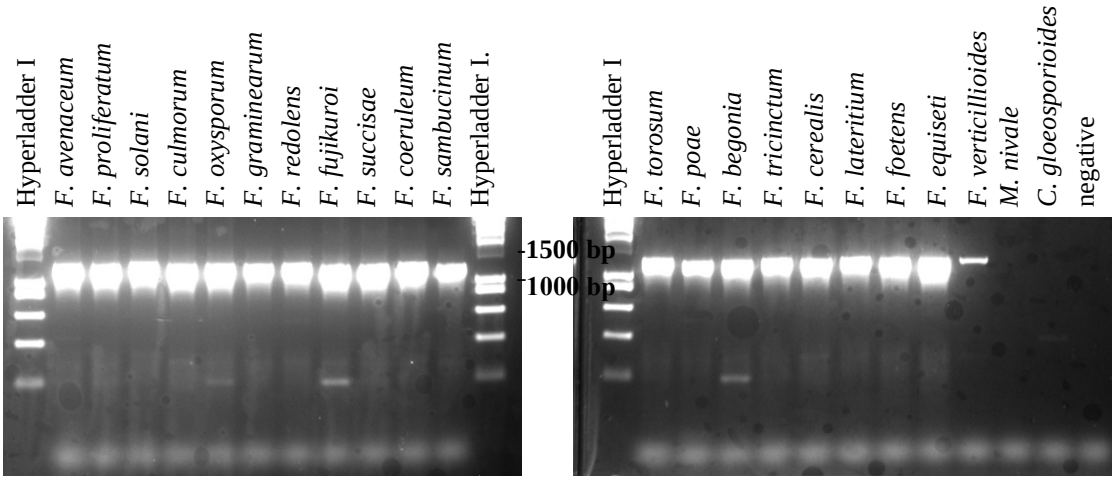

Figure 5. Banding pattern for the *Fusarium* genus-specific exTEFfor and FuexTEFrev primers tested on 20 *Fusarium* species, *Microdochium nivale* and *Colletotrichum gloeosporioides*. *M. nivale* and *C. gloeosporioides* were used as controls to test specificity of this reaction. ~1269 bp long product was amplified for all *Fusarium* species. Hyperladder I (Bioline) 10,000 bp molecular size marker was included in the first lane of each gel.

2.4.2 Characterisation of *Fusarium species* associated with *Allium* species in the UK

2.4.2.1 Distribution of isolates associated with basal rot of *Allium* species

The 10% Chelex 100 DNA extraction method (see Section 2.3.3.1) was suitable for PCR-based analysis, including amplification of single-copy targets (e.g. *TEF*). It is a quicker way of DNA extraction compared to the commercially available kits (from Qiagen and Sigma), but gave lower yield and quality of DNA (data not shown).

The *Fusarium* genus-specific primer pair (exTEFfor and FUexTEFrev) was used for primary classification of isolates which led to the identification of 299 *Fusarium* isolates (Table 5). The use of species-specific primer pairs (CLOX1/CLOX2 and CLPRO1/CLPRO2) revealed that the majority of isolates (205) obtained from the plant and soil samples collected were *F. oxysporum,* while only 15 isolates were identified as *F. proliferatum* (Table 5). The application of *F. oxysporum*- and *F. proliferatum*-specific primer pairs enabled the species level identification of 220 isolates, which left 78 isolates to be identified.

Fo: F. oxysporum, Fp: F. proliferatum, Fs: F. solani, Fr: F. redolens, Fc: F. culmorum, Fe: F. equiseti, Fav: F. avenaceum, Fac: F. acuminatum and *F*. sp.: *Fusarium* species

a: All isolates were identified by *Fusarium* genus- *F. oxysporum*- and *F. proliferatum*-specific primer pairs, additionally some isolates were also identified by *TEF* sequence similarity.

b: All isolates were identified by *Fusarium* genus specific primer pair and additionally some isolates were also identified at species level by *TEF* sequence similarity.

c: Isolates not been identified at species level

Of these 78 isolates, 44 were chosen based on origin and colony morphology for species-level identification by sequencing the *TEF* PCR products. Sequence comparison revealed the presence of *F. solani* (13 isolates), *F. redolens* (15 isolates), *F. culmorum* (7 isolates), *F. equiseti* (3 isolates), *F. avenaceum* (5 isolates) and *F. acuminatum* (1 isolate). Additionally, the identity of all *F. proliferatum* and 175 *F. oxysporum* isolates associated with *Allium* species was also confirmed by *TEF* sequencing (Appendix II). This approach enabled intra- and inter-specific genetic variation among *Fusarium* species associated with *Allium* species to be investigated. The remaining 34 *Fusarium* isolates associated with basal rot of *Allium* species isolates were not identified at species level.

F. oxysporum distribution

F. oxysporum was present in all mature onion, garlic, shallot samples, Dutch and Belgian sets and soil samples, but was not found in the leek samples or the French sets (Table 5). It was abundant in mature onion bulbs at every geographical location sampled including 16 fields across six English counties: Warwickshire, Bedfordshire, Essex, Suffolk, Lincolnshire and Nottinghamshire (Figure 6). *F. oxysporum* was also present in the Dutch and Belgian sets and the onion bulbs imported to the UK from four countries (Spain, Chile, the Netherlands and New Zealand).

F. proliferatum and *F. solani* distribution

F. proliferatum (15 isolates) was only isolated from onion plants in three different fields in the UK (Warwickshire, Bedfordshire and Lincolnshire) and from onion and garlic imported from Spain and Chile. *F. solani* (13 isolates) was found in

five onion samples (Bedfordshire, Essex, Suffolk and Lincolnshire) and from garlic and from soil collected in Suffolk (Figure 6).

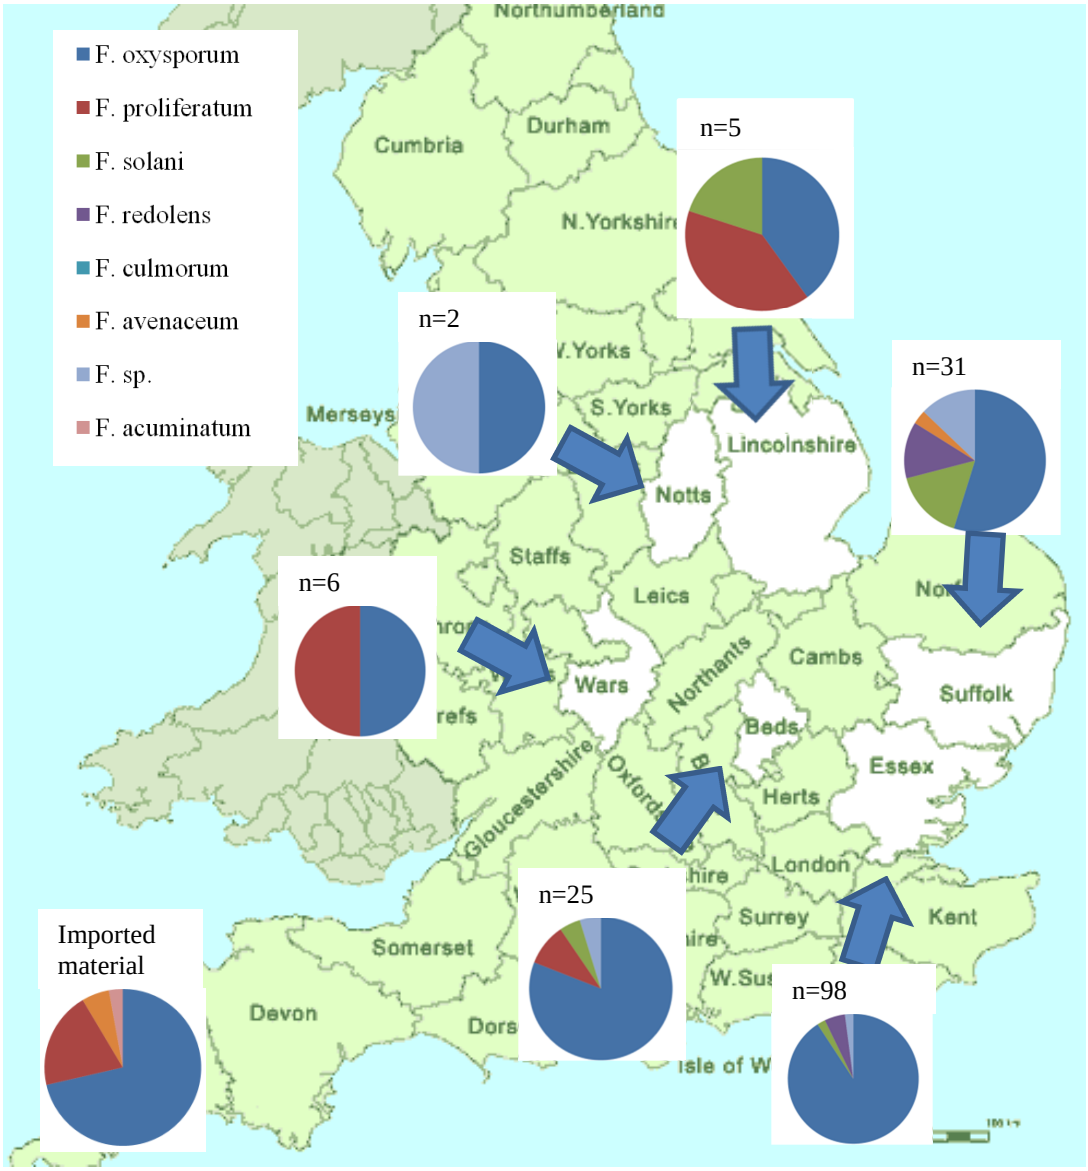

Figure 6. Origin and frequency of *Fusarium* species isolated from onion bulbs and sets in this study. Size of circles is not representative of the number of isolates obtained. Number of isolates (n) is shown next to corresponding pie chart.

F. redolens, F. avenaceum, F. acuminatum, F. culmorum and F. equiseti distribution

F. redolens (15 isolates) was recovered from soil and onions grown in Essex and Suffolk (Table 5; Figure 6). *F. avenaceum* (5 isolates) was recovered from

onions grown in Suffolk, Spanish onions, British leeks and French onion sets. One isolate of *F. acuminatum* was obtained from Spanish onions and one *F. culmorum* isolate was found in soil collected from a wheat field in Essex. Three isolates of *F. equiseti* were found in a soil sample collected in Essex.

Distribution of *Fusarium* species based on host and sample material

Six isolates obtained from leek were identified as *F. culmorum* and two as *F. avenaceum* (Table 5). Only *F. oxysporum* was found in shallot bulbs, while *F. oxysporum, F. solani* and *F. proliferatum* were found on garlic. *F. oxysporum* was identified in imported Dutch and Belgian sets and all imported onion bulbs (Table 5). Only one isolate of *F. avenaceum* was recovered from the French sets. The majority of the Chilean isolates (6) belong to *F. oxysporum* and only one isolate was identified as *F. proliferatum*. The Spanish onion batch was contaminated with *F. oxysporum* (8 isolates), *F. proliferatum* (6 isolates), *F. avenaceum* (1 isolate) and *F. acuminatum* (1 isolate).

***Fusarium* species from soil samples**

F. oxysporum was detected in every soil sample collected from fields where onions were grown either at the time of sampling or prior to sampling (Table 5). However, *F. proliferatum* was not present in any of the soil samples based on the results of species-specific PCR. Sequencing of the *TEF* gene also revealed the presence of *F. solani, F. redolens, F. culmorum, F. equiseti* and *F. avenaceum* in the soil of onion growing areas. A high proportion of isolates (53%) was identified as *F. oxysporum* from soil samples collected from a field in Warwickshire where onions were grown during the previous year (Table 6). A field in Suffolk (sample reference

6) was sampled a month after onion harvest in October 2009 where disease severely affected one half of the field (Table 6). Isolations from five soil samples (samples 1- to 5) collected from the symptomless part of the field led to the identification of two only *F. oxysporum* isolates from a total of six *Fusarium* isolates (33%). In contrast, 18 *Fusarium* isolates were obtained from the five soil samples collected from the diseased part (samples 6- to 10) of the field and 17 of them of them (88%) were identified as *F. oxysporum* (Table 6). *F. oxysporum* was less abundant (two out of 17 isolates, 12%) in a wheat field in Suffolk (sample reference 8) where soil was collected from in 2009, three years after onion was grown.

Table 6. Frequency of *Fusarium* spp. obtained from soil collected from three onion fields with onion basal rot incidence.

Fo: *F. oxysporum*, Fp*: F. proliferatum*, Fsp*: Fusarium* sp.
For sample reference number see Table 2

Intensive sampling within a single field

The same field in Suffolk (sample reference 8) was intensively sampled the following year (2010) when planted with onion. 70 onion bulbs were collected and

subjected to isolations which led to the identification of 28 *F. oxysporum* and three *F. redolens* (Table 5).

SUMMARY

British onion production is compromised by Fusarium basal rot, an increasing problem caused primarily by *F. oxysporum* f. sp. *cepae* (FOC). *F. proliferatum* causing basal rot of onion was found for the first time in three different counties in the UK. *F. oxysporum* was easily isolated from the soil of fields with a previous history of onion basal rot, even several years later, while *F. proliferatum* was only found from plant material. *F. solani* and *F. redolens* were found on onions grown in the UK as frequently (5%) as *F. proliferatum. F. avenaceum* was the least commonly found species from onion bulbs. Interestingly, isolations from greenhouse-grown leeks showing crown and basal rot symptoms led to the identification of *F. avenaceum* and *F. culmorum.* This is the first time these species have been found in the UK in diseased leeks. The presence of *Fusarium* species on imported onion sets and dry onion bulbs shows that this is one way in which pathogenic isolates can be introduced. Moreover, very aggressive FOC isolates were found from Dutch sets.

2.4.2.2 Cladistic analysis of *Fusarium* associated with *Allium* spp.

The *TEF* sequences of 197 *Fusarium* isolates, chosen based on host and origin, mainly derived from onion, but also from shallot, leek, garlic and Welsh onion from several locations were analysed by cladistics methods. Isolates clustered into seven main groups when analysed using the Neighbour-joining method (Figure 7). The seven groups were supported by high bootstrap values and corresponded to *F. oxysporum* (160 isolates), *F. proliferatum* (15 isolates), *F. solani* (13 isolates), *F.*

redolens (15 isolates), *F. culmorum* (7 isolates), *F. avenaceum* (5 isolates) and *F. acuminatum* (1 isolate).

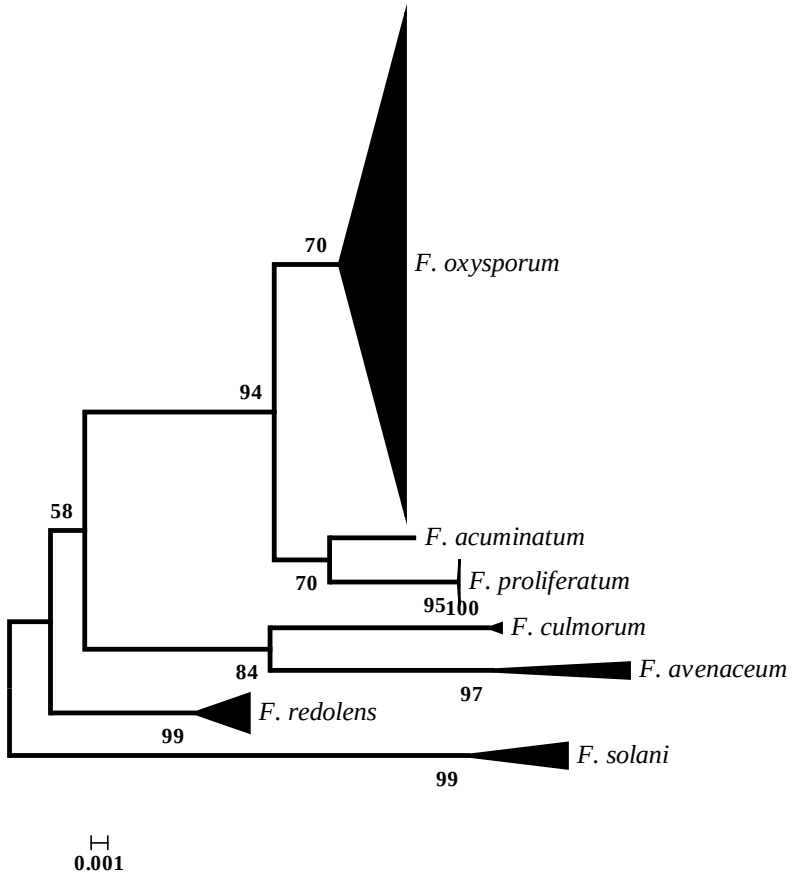

Figure 7. Cladogram of *Fusarium* species isolated from onion based on *TEF*. Consensus tree is shown with bootstrap values from 1000 replications. Triangles are representing. *Fusarium* species and the size of triangles are proportional to the number of isolates.

F. oxysporum TEF sequence variation

A UPGMA dendrogram (Figure 8) was produced comprising 47 of the 175 *F. oxysporum* isolates with *F. foetens* used as a closely related out-group. The selection of *F. oxysporum* isolates was made to represent different locations and *Allium* crops representing seven countries. To make this analysis more robust, eleven published *F. oxysporum* f. sp. *cepae* sequences deposited on NCBI were also included. *F. oxysporum* isolates associated with *Allium* species were subdivided into twelve sequence types (STs FoA – FoM), based on *TEF* sequence similarity (Kimura

distance =0.000) which was confirmed by maximum parsimony and neighbour-joining methods (data not shown). The most abundant sequence type was ST FoA with 136 isolates and ST FoB was also common with 37 isolates (Figure 8, Appendix II). The remaining sequence types were found less frequently: ST FoC (2 isolates), ST FoD (6 isolates), ST FoE (6 isolates), ST FoF (3 isolates), ST FoG (2 isolate), ST FoH (1 isolate) and ST FoI (3 isolates), ST FJ (7 isolates) and STs FoK – FoM which were represented by one isolate each (Figure 8, Appendix II).

The most common sequence types (FoA and FoB) were not associated with host or geographic origin (Appendix II). Sequence types FoA and FoB both comprised isolates from onion, garlic and leek. Moreover, isolates in ST FoA originated from Bedfordshire, Lincolnshire, Nottinghamshire, Warwickshire, Netherlands, Australia, USA and Ireland, while isolates belonging to ST FoB were recovered from Bedfordshire, Warwickshire, Suffolk, Lincolnshire, USA, Spain, New Zealand, and Italy. In addition, representatives of the two different STs were found in the same field (A25 and A28 from sample 4 in Bedfordshire, Appendix II).

A smaller group, ST FoC, comprised A5 and Fus1 isolates from onion grown in Nottinghamshire. ST FoD comprised isolates from British shallot (SH3, SH1-1) and from onions grown in Cambridgeshire (PG), Netherlands (151) and Uruguay (EU220399). Two isolates from British garlic and one *F. oxysporum* f. sp. *cepae* sequence from Germany formed ST FoE. Isolates recovered from Welsh onion from Japan (18 and 22) fell into ST FoF along with an isolate (D7-2b) recovered from Dutch onion sets. ST FoG comprised two isolates, one from onion grown in Suffolk (R3) and another from Turkey (EU220402).

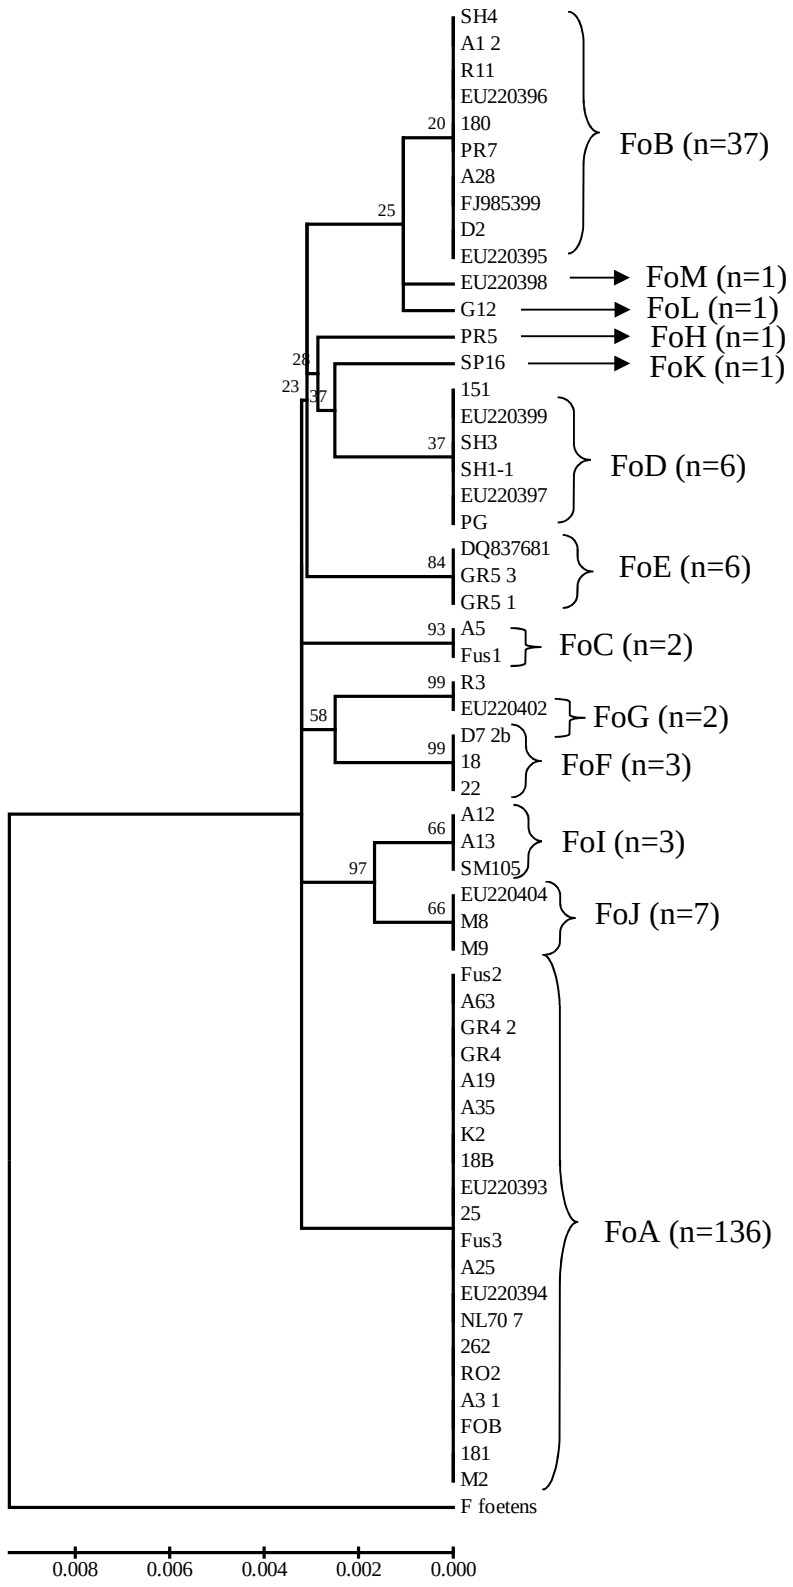

Figure 8. Dendrogram of representatives of *Fusarium oxysporum* associated with *Allium* species based on partial *TEF* dataset rooted with *F. foetens*. Consensus tree is shown with bootstrap values from 1000 replicates. GenBank accession number is indicated for each reference sequence. Twelve sequence types (FoA-FoM) were recognized. Sequence type frequencies of isolates (n) obtained during this study and used as references are shown in brackets.

A few isolates had unique STs including one of the Spanish isolates from leek (PR5, ST FoH) and another Spanish isolate from onion (SP16, ST FoK). Sequence types FoL and FoM also had only one representative each, from Dutch (EU220398) and British onions (G12) respectively.

Isolates from onion were represented in most of the ST groups such as FoA-FoE, FoG and FoI. Shallot isolates fell into ST groups FoB and FoD, while garlic isolates were represented in FoA, FoB and FoE.

The 28 *F. oxysporum* isolates from the intensively sampled field in Suffolk (sample reference 8) were identical based on the *TEF* sequence and they all fell into ST FoA. Similarly, all isolates from a field in Bedfordshire (sample reference 4), fields from Suffolk (sample references 9 and 11) and fields from Essex (sample references 5 and 6) belonged to ST FoA. One of the lower frequency sequence types, ST FoI, was recovered exclusively from a field in Bedfordshire (sample reference 3).

F. proliferatum TEF sequence variation

F. proliferatum isolates (18) derived from onion and one from garlic and an additional four published sequences which used for taxonomical reference were analysed by the neighbour-joining method (Figure 9). The *F. proliferatum* isolates from onion formed three sequence types (FP1-FP3), while the one garlic isolate belonged to FP4 (Figure 9, Appendix III). Three isolates representing FP3 originated from Spain, while FP1 and FP2 comprised isolates from more than one country. For example, eleven isolates belonging to FP1 were recovered from onions grown in Warwickshire, Lincolnshire, Ireland, Spain, USA, Chile, Netherlands and Uruguay. FP2 comprised six isolates from Warwickshire, Bedfordshire, Netherlands and

Argentina. Representatives of two sequence types were also present in the same field (e.g. A40 and A8 from sample 4 Bedfordshire, Appendix III).

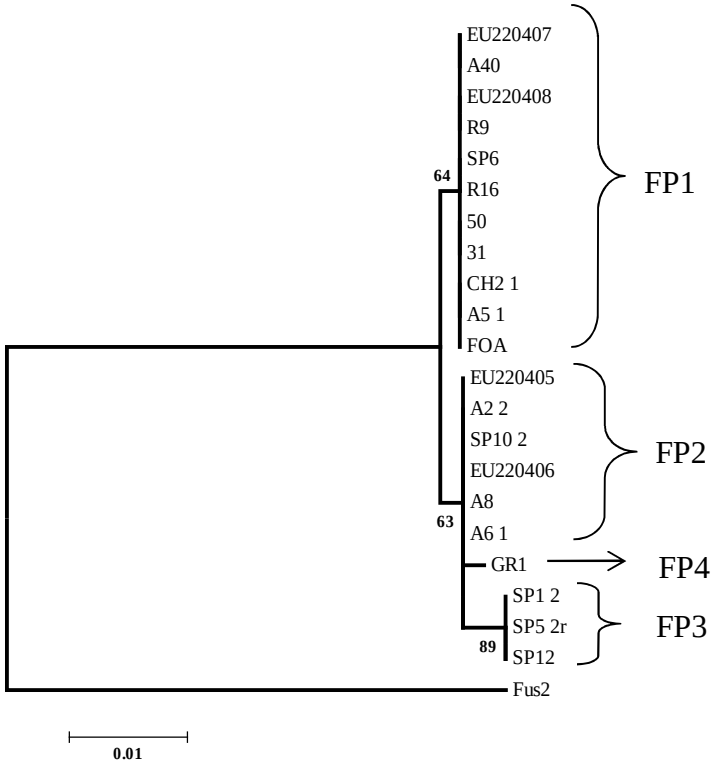

Figure 9. Cladogram of *Fusarium proliferatum* isolated from onion and garlic based on *TEF* rooted with *F. oxysporum* f. sp. *cepae* isolate Fus2. GenBank accession number is indicated for each reference sequence. Consensus tree is shown with bootstrap values from 1000 replications. Four sequence types were recognised (FP1-FP4).

F. redolens TEF sequence variation

F. redolens isolates (15) originating from Suffolk and Essex and collected from onion bulbs and soil comprised six sequence types (FR1-FR6) based on the neighbour-joining method (Figure 10, Appendix III). All isolates that originated from Essex shared the same sequence type, FR1, except NL41 (FR2). Isolates from Suffolk showed higher variation, every isolate falling into a different sequence type group.

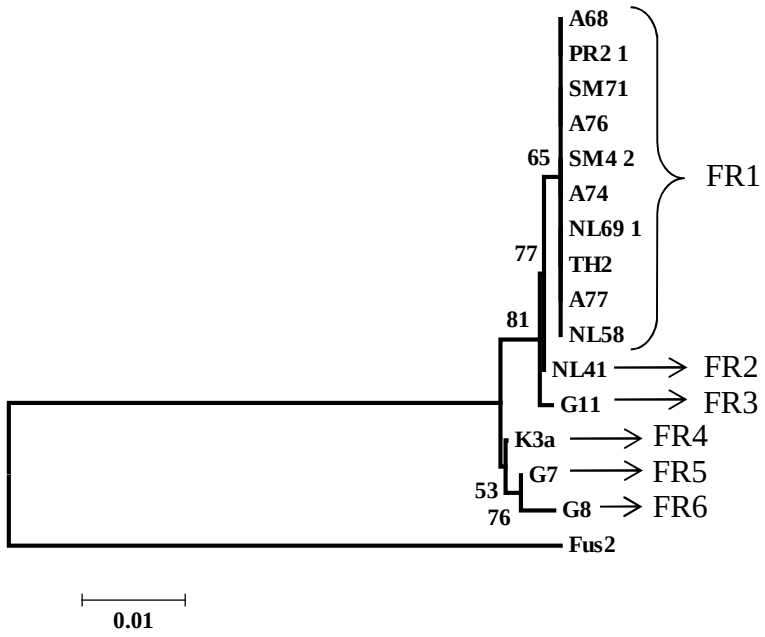

Figure 10. Cladogram of *Fusarium redolens* isolated from onion based on *TEF* rooted with *F. oxysporum* f. sp. *cepae* isolate Fus2. Consensus tree is shown with bootstrap values from 1000 replications. Six sequence types were recognised (FR1-FR6).

F. solani TEF sequence variation

F. solani isolates (13) analysed by the neighbour joining method based on *TEF* sequence (Figure 11, Appendix III) fell into seven sequence type groups (FS1-FS7). Fus2, a *F. oxysporum* isolate was used as out-group. *F. solani* isolates were collected from onion, garlic and soil and originated from Suffolk, Essex, Bedfordshire and Lincolnshire. The only garlic isolate from Bedfordshire (GR5_4)

formed a distinct sequence type (FS4). FS1 comprised isolates from Suffolk and Essex both from onion and soil, while isolates belonging to FS6 originated from Essex, Lincolnshire and Bedfordshire. The remaining isolates formed individual sequence types.

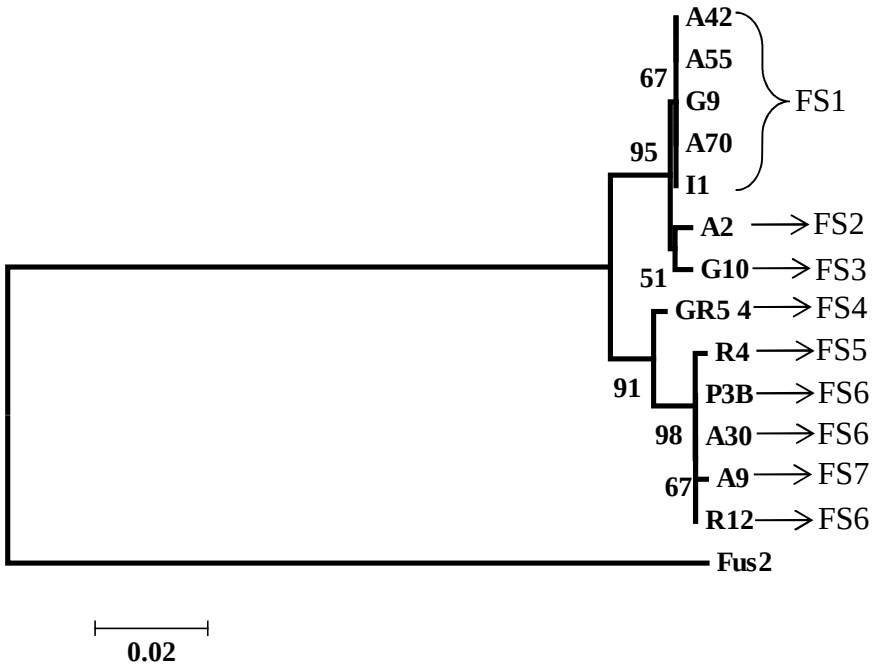

Figure 11. Cladogram of *Fusarium solani* isolated from onion and garlic based on *TEF* rooted with *F. oxysporum* f. sp. *cepae* isolate Fus2. Consensus tree is shown with bootstrap values from 1000 replications. Seven sequence types were recognised (FS1-FS7).

F. avenaceum, F. culmorum and *F. equiseti TEF* sequence variation

Six *F. avenaceum* isolates from British onion and leek with one additional sequence used as taxonomic reference (EU220414) were analysed based on *TEF* sequences using the neighbour joining method (Figure 12, Appendix III). Two isolates derived from leeks grown in Cambridgeshire were identical and formed sequence type FA1. The rest of the isolates were different and fell into individual sequence types (FA2 – FA6). *F. culmorum* isolates obtained from leek and soil all had identical *TEF* sequences so formed only one ST (Appendix III). Similarly, three

F. equiseti isolates from the soil of one particular field again formed one sequence type group (Appendix III).

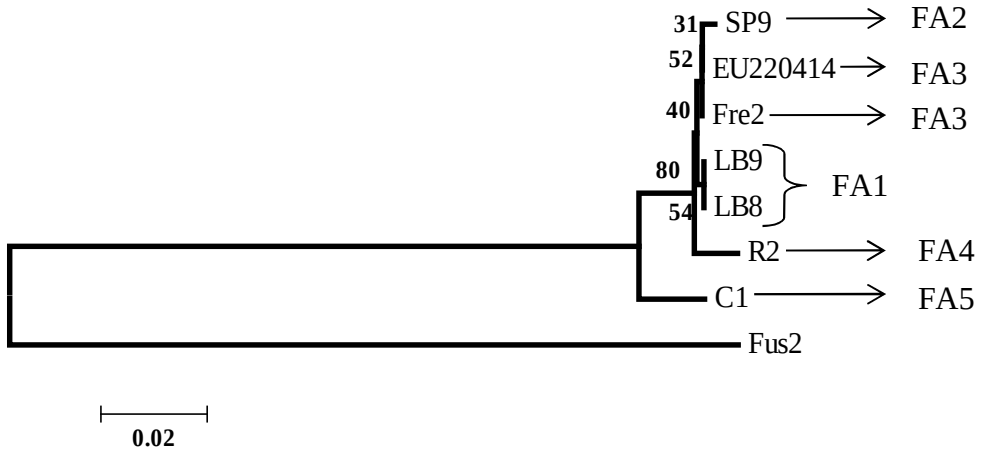

Figure 12. Cladogram of *Fusarium avenaceum* isolated from onion and leek based on *TEF* rooted with *F. oxysporum* f. sp. *cepae* isolate Fus2. GenBank accession number is indicated for each reference sequence. Consensus tree is shown with bootstrap values from 1000 replications. Four sequence types were recognised (FA).

SUMMARY

The *TEF* sequences of 197 *Fusarium* isolates from onion, shallot, leek, garlic and Welsh onion from several locations were analysed by cladistics methods. Isolates clustered into seven main groups supported by high bootstrap values and corresponded to *F. oxysporum* (160 isolates), *F. proliferatum* (15 isolates), *F. solani* (13 isolates), *F. redolens* (15 isolates), *F. culmorum* (7 isolates), *F. avenaceum* (5 isolates) and *F. acuminatum* (1 isolate). Representatives of each of these species were further analysed by comparing their *TEF* sequences to previously published sequences of *Fusarium* isolates associated with onion basal rot. Results of the sequence analysis of *TEF* suggest that *F. oxysporum* associated with onion basal rot in the UK is composed of at least nine different sequence types (STs FoA-FoL). The *F. proliferatum* isolates from onion formed three sequence types (FP1-FP3), while

the one garlic isolate belonged to FP4. *F. redolens* isolates (15) comprised six sequence types (FR1-FR6), *F. solani* isolates (13) seven sequence types (FS1-FS7), and *F. avenaceum* (5) five sequence types (FA1-FA5). *F. culmorum* (7) isolates did not show any *TEF* sequence variation. In general, sequence types were not associated with host or geographic origin.

2.5 DISCUSSION

2.5.1 Testing and development of primer pairs used for *Fusarium* identification

Identification of fungal species is traditionally based on morphological characteristics. Identification of *Fusarium* species based on morphology is reliable if done by well-trained staff, but the recent development of molecular methods provides the opportunity for a quicker and more reliable identification of *Fusarium* by researchers without any prior knowledge of *Fusarium* taxonomy. The other great advantage of molecular methods is that they do not necessarily require pure cultures as infected plant samples can also be used. *TEF* is the most widely used molecular marker for *Fusarium* species identification and ideally requires sequence comparison with type isolates (Geiser *et al.*, 2004; Park *et al.*, 2010). In some cases, e.g. *Fusarium graminearum* species complex, multi-locus genotyping is required for species-level identification (Ward *et al.*, 2008). Molecular methods are expensive and therefore cost effective DNA extraction methods and the use of *Fusarium* genus- and species-specific primers were tested.

The 10% Chelex 100 DNA extraction method was suitable for PCR-based analysis, including amplification of single-copy targets (e.g. *TEF*). It is a quicker and more cost effective way of DNA extraction compared to the commercially available kits (from Qiagen and Sigma), but gave poorer quality and lower amounts of DNA.

Two *Fusarium* genus-specific primer pairs based on the ITS region of the rDNA published in the literature were tested. The *Fusarium*-specific primer pair (FU-ITSf/FU-ITSr) published by Bluhm *et al*. (2004) was more reliable than the sequences (ITS-FUf/ITS-Fur) designed by Abd-Elsalam *et al*. (2003). Only *F.*

oxysporum, F. solani, F. verticillioides and *Rhizoctonia solani* sequences were used by Abd-Elsalam *et al.* to test primer design, while Bluhm *et al.* utilised nine *Aspergillus* spp., nine *Fusarium* spp., and ten *Penicillium* spp. sequences. Differences in the number of species representing different genera used to test primer pairs could explain the differences in specificity.

F. oxysporum and *F. proliferatum*-specific PCRs (CLOX1/CLOX2 and CLPRO1/CLPRO2; Mule *et al.,* 2004) were potentially suitable for distinguishing these two species based on presence / absence of amplicons, but the representatives of other *Fusarium* species had to be identified based on *TEF* sequencing.

Newly developed *Fusarium* genus-specific primers based on *TEF* were designed to accelerate the identification of *Fusarium* isolates (exTEFfor and FUexTEFrev). Initially, the specificity of these primers was tested *in silico* on 12 fungal species, including four *Fusarium* and eight closely related species. These were also successfully tested *in vitro* on 20 *Fusarium* species and a few closely related species (*M. nivale* and *C. gloeosporioides*) and proved to be a rapid and reliable method for identifying *Fusarium* species associated with *Allium* crops. During this three-year-project about 300 *Fusarium* isolates were identified using the newly developed primer pair and the identity about 200 of these was confirmed by sequencing the *TEF* gene. All of these sequences belonged to the representatives of *Fusarium* genus. Nevertheless, the robustness of identification using newly developed primer pair (exTEFfor and FUexTEFrev) could be enhanced by testing its specificity *in vitro* on several fungal genera.

Recent publications on onion basal rot have reported the use of morphological identification and combined with *Fusarium* species-specific primers but isolates belonging to *F. solani* had to be identified based on *TEF* sequencing

(Bayraktar *et al*., 2010; Galvan *et al*., 2008). Sequences of primer pairs applicable for the identification of *F. solani* and the *Fusarium* genus based on *TEF* have only been published earlier this year (Arif *et al*., 2012).

2.5.2 Genetic diversity of *Fusarium* species associated with *Allium* species in the UK

Onion basal rot incidence came to the attention of British growers and agronomists recently, because there has been a considerable increase in disease levels in the last few years (A. Richardson, Allium and Brassica Centre pers. comm.). This is the first comprehensive study which has investigated the identity of pathogens causing onion basal rot in the UK as well as their genetic variation.

F. oxysporum was the most commonly isolated species from onion bulbs collected between the 2008 and 2010 in the UK and this is consistent with previous findings from the Netherlands and Turkey (Bayraktar *et al*., 2011; Galvan *et al*., 2008). *F. proliferatum* was found for the first time in the UK in onions with basal rot symptoms collected in three different counties. *F. proliferatum* has been identified as a causal agent of basal rot in other countries (Galvan *et al*., 2008, du Toit *et al.*, 2003, Stankovic *et al*., 2007). *F. proliferatum* infecting onion, may affect the health safety of agricultural workers as well as consumers. Fumonisin B1, beauvericin, fusaric acid, fusaproliferin and moniliformin production of *F. proliferatum* stains isolated from onion and garlic were confirmed by Stankovic *et al.* (2007) and Seefelder *et al*. (2002). Fumonisin B1 has been linked to human cancer and mycotoxicosis (Gelderblom *et al*., 1991). Beauvericin, fusaproliferin, moniliformin and fusaric acid has been found toxic to various human cell lines (Logrieco *et al*., 2002; Logrieco *et al*., 1996; Celik *et al*., 2009), Additionally, Fumonisin B1was found to cause chromosomal aberrations in onion cells (Lerda *et al*., 2005). Moreover, all these toxins are considered as phytotoxins, therefore suspected to be involved in the expression of symptoms on onion (Stankovic *et al*., 2007). However, further studies

have to be carried out in terms of *in vitro* and *in planta* toxin production to evaluate risk to plant and human health.

F. solani and *F. redolens* were found on onions grown in the UK as frequently as *F. proliferatum*. Both species were reported as pathogens of onion in Turkey, and Serbia (Bayraktar *et al*., 2010; Klokocar-Smit *et al*., 2008). *F. avenaceum* was the least commonly found species from British grown onion bulbs which agrees with previous findings from the Netherlands (Galvan *et al.*, 2008). A few *F. equiseti* isolates were recovered from the soil of one of the fields in Essex. *F. equiseti* is a common soil saprotroph and also can be associated with head blight of cereals (Nicholson *et al*., 2003).

Interestingly, isolations from greenhouse-grown leek showing basal rot symptoms led to the identification of *F. culmorum* and *F. avenaceum*. This is the first time these species have been found in the UK in leek with crown and basal rot symptoms. *F. culmorum* was previously identified as the causal agent of basal rot of leek in Spain and California (Armengol *et al*., 2001; Koike *et al*., 2003) and was also reported as an onion pathogen in the Netherlands (Galvan *et al*., 2008). *F. avenaceum* has been identified as the causal agent of crown rot of leek (Hall *et al*. 2007). Moreover, both species are associated with Fusarium head blight of cereals in the UK (Nicholson *et al*., 2003). Although, *F. oxysporum* was not found in diseased greenhouse-grown British leeks, it has been recently isolated from field-grown leek showing basal rot symptoms (Andrew Taylor, University of Warwick, pers. comm.).

F. oxysporum was also present on shallot and garlic showing basal rot symptoms in the UK. These results agree with previous publications (Sintayehu *et al*., 2011, Palmero *et al*., 2012.). Additionally, *F. proliferatum* and *F. solani* were also isolated from garlic. *F. proliferatum* was confirmed as causal agent of basal rot

of garlic in Spain, Serbia, USA, China and Italy (Palmero *et al*., 2012, Stankovic *et al*., 2007, Dugan *et al*., 2007; Tonti *et al*., 2012). *F. solani* has not been reported from garlic before, although its pathogenic ability has yet to be confirmed.

The presence of *Fusarium* species on imported onion sets and dry onion bulbs shows that this is one way in which pathogenic isolates can be introduced. *F. oxysporum* was found from Dutch sets showing basal rot symptoms and on symptomless Belgian import sets. The fields where the Dutch and Belgian sets were planted suffered from onion basal rot although the disease had not been reported in the area previously (A. Richardson, A & B Centre, pers. comm.). These results suggest that new outbreaks of *Fusarium* might be caused by the import of diseased onion sets, and hence suggest that closer inspection of such planting material is required. Spanish, Chilean and Dutch imported onion bulbs showing basal rot symptoms were mainly infected by *F. oxysporum*. Moreover, *F. proliferatum* was recovered from Spanish and Chilean imported onion bulbs. Almost half of the isolates from the Spanish sample belonged to *F. proliferatum* and the two less common species, *F. acuminatum* and *F. avenaceum*, were also present. Most diseased onions are discarded during the grading process in the storage facilities, but some symptomless bulbs may develop disease during transport and storage.

F. oxysporum was easily isolated from the soil of fields with a previous history of onion basal rot, even several years later. A high proportion of the isolates obtained from a severely diseased part of a field in Suffolk were identified as *F. oxysporum*. More than 50% of isolates collected from a field in Warwickshire (five months after harvest) were identified as *F. oxysporum*. It was also present in soil from a field in Essex where onions had not been grown for 3 years. This same field was sampled intensively for decaying bulbs the following year and had a very high

level of basal rot. This suggests that the level of propagules is very high by the end of the onion growing season and that the pathogen does survive several years in soil. This is not unexpected as the decaying bulbs are not collected (pers. observation) and removed from the fields and the grower only uses a 4-year-rotation. *F. oxysporum* can survive on soil debris as mycelium or as chlamydospores (Abawi and Lorbeer, 1972). Interestingly, *F. proliferatum* was only found from plant material, which could be due to lack of chlamydospore production (Leslie and Summerrell, 2006) or because *F. proliferatum* mainly causes disease in storage. A few other isolates were also identified as *F. equiseti, F. culmorum* and *F. redolens* which commonly occur in soils. *F. equiseti* and *F. culmorum* are also associated with head blight of wheat which is grown in rotation with onion (O`Connor, 2005).

Results of the sequence analysis of *TEF* suggest that *F. oxysporum* isolates associated with onion basal rot in the UK are composed of at least nine different sequence types (STs), suggesting that pathogenic ability may have evolved convergently. Transfer of pathogenicity-related genes of *F. oxysporum* f. sp. *lycopersici* by parasexuality and horizontal gene transfer have been proposed (Ma *et al*. 2010). Several VCG groups have been identified within FOC (Swift *et al*., 2002; Southwood *et al*., 2012) which also indicates genetic variation. FOC isolates have different levels of aggressiveness which suggests that lineages may also have different pathogenic properties (Taylor *et al*., 2012). Moreover, the *TEF* sequence types of FOC cannot be explained by the current geographic distribution. It was not uncommon to recover only one sequence type from one particular field. For instance, all *F. oxysporum* isolates recovered from the intensively sampled field in Essex belonged to the same sequence type “FoA” suggesting a clonal origin. This lack of

geographic association may due to human activity *e.g.* global trade of planting material and therefore the spread of onion basal rot (Galvan *et al*., 2008).

During this study six *Fusarium* species were identified on diseased *Allium* crops in the UK, namely *F. oxysporum, F. proliferatum, F. solani, F. redolens, F. culmorum* and *F. avenaceum.* The role of these species needed to be defined (e.g. pathogen, facultative pathogen and saprophyte), in order to manage diseases and to develop methods applicable for identification of pathogenic forms. The pathogenicity of these different species on onion is examined in Chapter 3.

CHAPTER 3

MOLECULAR IDENTIFICATION AND CHARACTERISATION OF *FUSARIUM OXYSPORUM* FORMAE SPECIALES

3.1 INTRODUCTION

3.1.1 Molecular techniques used for characterisation of *F. oxysporum* pathogen populations

The use of various molecular methods in order to distinguish *F. oxysporum* formae speciales (ff. spp.) has led to the same conclusion: most formae speciales are polyphyletic, but with a few exceptions (Leslie and Summerell, 2006). This section gives a short summary of the various methods and genes used over the last twenty years, which led to above conclusion.

Restriction fragment length polymorphisms (RFLP) is used for the analysis of populations as genomic DNA of different isolates may result in a distinct pattern after digestion with various restriction enzymes and separation by electrophoresis. Variations are generated by mutations that create or abolish recognition sites for these enzymes or change the length of the fragment (NCBI). RFLP gives information on genetic diversity by covering the whole genome and is reproducible but requires large amounts of DNA. *F. oxysporum* ff. spp. *cubense*, *dianthi*, *gladioli*, *lycopersici*, *niveum,* and *vasinfectum* were found to be polyphyletic while *F. oxysporum* f. sp. *albedinis* was monophyletic based on their RFLP pattern (Elias *et al*., 1993; Fernandez *et al*., 1998; Kim *et al*., 1992, Manicom and Baayen; 1993; Koenig *et al*, 1997; Mes *et al.*, 1994; Tantaoui *et al*, 1996).

Random amplified polymorphic DNA (RAPD) markers are PCR amplicons of random segments of genomic DNA with a short single primer (Williams *et al*., 1990). RAPD is a cheap and powerful method for the characterization of species, but it can be difficult to reproduce the same results (*i.e*. laboratory dependent). Specific bands can be identified based on amplicon-pattern and be used to develop sequenced characterized amplified region markers (SCARs). Using RAPD markers, *F.*

oxysporum ff. spp. *batatas, cubense, cucumerinum, dianthi, gladiolus, nicotianae, phaseoli, pisi,* and *radicis-cucumerinum* were found to be polyphyletic while *F. oxysporum* f. sp. *ciceris* was described as a monophyletic f. sp. (Alves-Santos *et al*., 2002; Bentley *et al*., 1995; Clark *et al*., 1998; Haan *et al*., 2000; Grajal-Martin *et al*., 1993; Wright *et al*., 1996; Lievens *et al*., 2007; Manulis *et al*., 1993, Vakalounakis *et al*., 2004; Jiménez-Gasco *et al*., 2002).

A less frequently used fingerprinting method is AFLP analysis, which involves the fragmentation of total genomic DNA and the selective amplification of fragments (Vos *et al*. 1995). The advantage of using this method is that it covers the whole genome and is reproducible. Conversely, it is more expensive and time consuming. The monophyly of *F. oxysporum* ff. spp. *lilii* and *tulipae* were supported by AFLP profiles, but *F. oxysporum* ff. spp. *asparagi, cepae, cubense, dianthi, gladioli, lini, opuntiarum* and *spinaciae* were found to be polyphyletic (Baayen *et al*., 2000; Galvan *et al*., 2008; Groenewald *et al*., 2006).

Multi-locus sequence typing (MLST) offers a robust approach for characterizing the genetic diversity in the *F. oxysporum* species complex (O'Donnell *et al*., 2009).

Translation elongation factor 1α subunit (*TEF*) and intergenic spacer of rDNA (*IGS*) have been found to be highly informative markers which are sensitive to evolutionary change. A two-locus DNA database was constructed based on partial *TEF* and *IGS* sequences of 850 *F. oxysporum* isolates representing various formae speciales (O`Donnell *et al*., 2009). Nearly 300 (256) two-locus sequence types were differentiated and the dataset suggested that two-thirds of them may be associated with a single host plant.

Microsatellites (simple sequence repeats, SSR) are 2-6 base pair sequence repeats which can vary among isolates of the same species or related species and therefore can be used as molecular markers. Microsatellites were employed to study genetic diversity of *F. oxysporum* ff. spp. *lycopersici, radicis-lycopersici, ciceris* and soil isolates (Barve *et al*., 2001; Bayraktar *et al*., 2008; Jimenez-Gasco *et al*., 2004; Balmas *et al*., 2005; Bogale *et al*., 2006). Analysis of these data revealed the stepwise evolution of eight races of *F. oxysporum* f. sp. *ciceris* when multiple gene genealogies failed due to lack of polymorphism (Jimenez-Gasco *et al*., 2004).

3.1.4 Specific identification of *F. oxysporum* formae speciales

Members of the *F. oxysporum* species complex have been characterised using biotypic and molecular methods in an attempt to identify agriculturally important pathogenic isolates.

Pathogenicity assays provide a robust solution for distinguishing various formae speciales, but this involves the infection of more than a hundred plant species which is very time consuming and laborious (Leslie and Summerell, 2006).

Vegetative compatibility provides another widely used biotypic characterisation method that is based on the ability of isolates to anastomose and form heterokaryons within vegetative compatibility groups (VCGs) (Katan, 1999). A worldwide collection of *F. oxysporum* f. sp. *lycopersici* isolates was characterized by the VCG method and molecular methods subsequently revealed that isolates within each VCG are clonal derivatives of a common ancestor. Therefore, VCGs are reliable indicators of evolutionary origin and appear to be clonal lineages (Elias *et al*., 1993).

Molecular variation in populations of *F. oxysporum* ff. spp. *cucumerinum*, *radicis-cucumerinum, ciceris* (races 0, 1A, 5, and 6), *dianthi* (race 1), *basilica* and *phaseoli* was analysed to develop PCR-based markers (RAPD and more specific SCAR markers) for distinguishing amongst formae speciales and races (Lievens *et al*., 2007; García-Pedrajas *et al*., 1999; De Haan *et al*., 2000; Chiocchetti *et al*., 2001; Alves-Santos *et al*., 2002; Jiménez-Gasco and Jiménez-Díaz, 2003; Kelly *et al*., 1998; Pasquali *et al*., 2006).

Transposable elements can also be used for the specific identification of various formae speciales. *F. oxysporum* f. sp. *albedinis*, a pathogen of date palm, and *F. oxysporum* f. sp. *chrysanthemi*, a pathogen of Paris Daisy were specifically detected based on the differences in the transposable element, *Fot1* sequence (Fernandez *et al*., 1998; Pasquali *et al*., 2004a; Pasquali *et al*., 2004b). Primers designed to amplify *Fot1* and *impala* elements allowed the differentiation of *F. oxysporum* f. sp. *dianthi* races 1, 2, 4, and 8 (Chiocchetti *et al*., 1999). *F. oxysporum* f. sp. *lactucae* race 1 and *F. oxysporum* f. sp. *cepae* (FOC) VCG 0425 and 0421 isolates were detected by an inter-retrotransposon sequence-characterized amplified region technique which employed primers designed on long terminal repeats, *Skippy* and *Han*-solo (Pasquali *et al*., 2007; Southwood *et al*., 2012).

Housekeeping genes are useful for investigating the phylogeny of fungi, however, this seldom correlates with the pathogenic ability of plant pathogens, therefore in these cases housekeeping genes can be used to develop specific identification / detection methods (Talhinhas *et al*., 2002; Barbara and Clewes, 2003). For example, *Colletotrichum acutatum* isolates causing anthracnose on lupin form a distinct clade, based on ITS sequence, from other pathogenic forms within this species (Talhinhas *et al*., 2002).

Based on single nucleotide polymorphisms present in the *IGS* region, PCR diagnostic tools were developed to detect the *F. oxysporum* f. sp. *cubense* tropical race 4 (Dita *et al*., 2010).

Metabolic enzymes have been used to distinguish variation in *F. oxysporum* f. sp. *lycopersici* and *radicis-lycopersici* and races of *F. oxysporum* f. sp. *lycopersici* originating from Japan, including endo-polygalacturonase (*PG1*) and exo-polygalacturonase (*PGX4*) sequences (Hirano and Arie, 2006).

And finally, effector genes are beginning to provide a useful means for identifying *F. oxysporum* formae speciales and races (Rep *et al*, 2004; Lievens *et al*., 2009ab). For instance, specific detection of *F. oxysporum* ff. spp. *lycopersici* (races 1-3) and *vasinfectum* isolates was achieved based on the presence and sequence polymorphism of the *SIX* (secreted in xylem) and *PEP* (putative effector protein; Lievens *et al*., 2009a; Chakrabarti *et al*., 2011). *F. oxysporum* isolates have been previously screened for the presence of seven *SIX* genes encoded on a mobile pathogenicity chromosome (MPC) (Lievens *et al*., 2009a; Ma *et al*., 2010); *SIX1-SIX5* were only found in *F. oxysporum* f. sp. *lycopersici* isolates, *SIX6* and *SIX7* were present in a few other formae speciales, such as *melonis, lilii* and *racicis-cucumerinum.* A recent study on *F. oxysporum* f. sp. *cubense* reported the presence of homologues of *SIX1*, *SIX7* and *SIX8* (Meldrum *et al*., 2012). Homologues of *SIX1, SIX4, SIX8* and *SIX9* were identified in a *F. oxysporum* strain infecting *Arabidopsis thaliana* (Thatcher *et al*., 2012). Another highly expressed gene, *Fusarium* transcription factor 1 (*FTF1*), was identified during the infection of *F. oxysporum* f. sp. *phaseoli*, and it is also present in *F. oxysporum* f. sp. *lycopersici* (Ramos *et al*., 2007).

3.2 AIMS AND OBJECTIVES

The specific objectives of this chapter were:

1. To test the pathogenicity of different isolates of *Fusarium* species derived from *Allium* crops and of representatives of different formae speciales in an onion seedling bioassay.

2. To characterise *F. oxysporum* f. sp. *cepae* (FOC) isolates and other formae speciales based on housekeeping and effector gene sequences and microsatellites.

3. To compare the results of the pathogenicity assay with multigene sequence and microsatellite data.

3.3 MATERIALS AND METHOD

This Chapter describes the molecular methods and onion seedling assay used for the characterisation of *Fusarium* isolates (Figure 13). *Fusarium* isolates from diseased *Allium* species were previously characterised based on *TEF* sequences (Chapter 2). In this chapter, using the *TEF* sequences of these *F. oxysporum* isolates additional isolates representing several formae speciales were identified as identical based on their *TEF* sequence similarity.

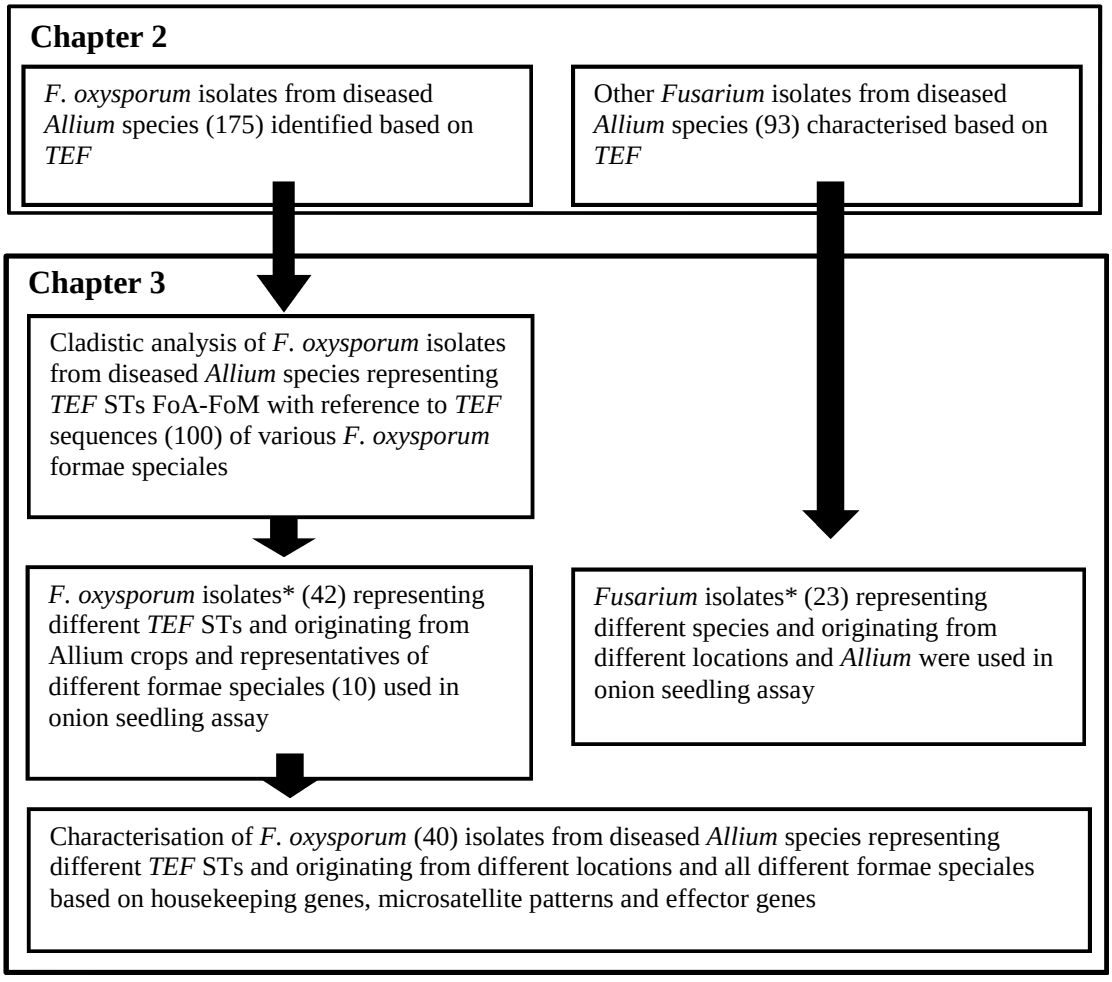

Figure 13. Flow-chart of steps used for the characterisation of *Fusarium* isolates from diseased *Allium* species.

Following this, representatives of *Fusarium* species associated with basal rot symptoms and representatives of several different formae speciales were then used in an onion seedling assay to determine aggressivess. Based on combined results of *TEF* sequence data and the onion seedling assay, *F. oxysporum* isolates were then chosen to be further characterised based on sequences of housekeeping genes, microsatellites and effectors (Figure 13).

3.3.1 Cladistic analysis of *F. oxysporum* isolates associated with diseased *Allium* species and different formae speciales based on *TEF* sequences

To initially define how *F. oxysporum* isolates obtained from diseased *Allium* species related to the three clades of the *F. oxysporum* species complex published by O'Donnell *et al*. (1998a; Figure 1), 28 *TEF* sequences of *F. oxysporum* isolates associated with diseased *Allium* species along with 35 sequences used in the research paper mentioned above were analysed using maximum likelihood method (Felsenstein, 1981) by running PAUP* b10 (Swofford, 1997) interference from inside Geneious^{TM} Pro v5.4 (Drummond *et al*., 2011).

A second method, cladistics, was also used to analyse genetic relationships among *F. oxysporum* isolates from diseased *Allium* species within the *F. oxysporum* species complex. *TEF* sequences of *F. oxysporum* isolates from diseased *Allium* species representing *TEF* STs FoA-FoM (see Chapter 2, Appendix II) along with sequence data of 100 representatives of 39 formae speciales published by O'Donnell *et al*., (1998), Baayen *et al*. (2000), Wunsch *et al*. (2009) and Galvan *et al*. (2008) were analysed by the neighbour-joining method (Saitou and Nei, 1987) using MEGA 4.0 (Tamura *et al*., 2007). To assess the topology of branches, bootstrap (Felsenstein, 1985) analysis was performed with 1000 replicates.

3.3.2 Onion seedling assay of *Fusarium* isolates from diseased *Allium* species

The aggressivess of 52 *Fusarium* isolates was tested on onion cv. Hystar F1 (Elsoms, UK) using a seedling test described by Taylor *et al*. (2012). Isolates were grown on PDA medium for ten days at 22°C at 12 hours light/dark cycle. Sterile distilled water (9 ml) was pipetted onto each plate and spores were released by using an L-shape spreader. The suspensions were filtered separately through sterile glass wool to remove hyphal fragments. Spores were counted in a haemocytometer and diluted in sterile distilled water to 1 x 10^6 spores/ml in a final volume of 5 ml. Onion seeds (112) were inoculated by incubation for one hour in the spore suspension. Onion seeds soaked in sterile distilled water were used as control. Fus2, a very aggressive FOC isolate, was used as positive standard and a *F. oxysporum* isolate Fo47 (a non-pathogenic biocontrol agent; Alabouvette *et al*., 2007), as a non-aggressive control (negative standard). Fifteen *Fusarium* isolate treatments were set up per experiment including the Fus2 and water treatment (Appendix IV). For each treatment, inoculated onion seeds (112) were sown individually into four 4x7-well-trays containing Levingtons F2 compost (Scotts) and grown at 25°C day and 18°C night under cycles of 16 hours light/8 hours dark. Trays were arranged in a randomized block design within a glasshouse compartment over two benches (Figure 14). Trays were watered through matting for four weeks and at the end of this period the numbers of surviving seedlings were recorded. A survival index was calculated for each treatment in a residual maximum likelihood (REML) procedure for linear mixed models on angular-transformed data with GENSTAT v. 13 (VSN International). The REML procedure was chosen over ANOVA to include row and column effects, because the seedling assay design was unbalanced. The model for the

analysis consisted of random factors (date, row and column) and a fixed factor (treatment).

Isolates significantly not different (l.s.d. 5%) from Fus2 (positive control) were considered very aggressive. Isolates significantly different from both Fus2 and Fo47 (negative control) were considered as moderately aggressive, while those not significantly different from Fo47 were considered as non-aggressive. Highly and moderately aggressive isolates were termed *F. oxysporum* f. sp. *cepae*.

In total *F. oxysporum* and other species isolates (74) from diseased onion, leek, shallot and garlic were chosen based on their *TEF* sequences to be tested in onion seedling assay (Table 7). Additionally, ten *F. oxysporum* isolates representing several different formae speciales were also included (Table 7).

Additionally, 14 *F. oxysporum* isolates (Fus2, 180, D2, NL96, A13, Fus1, A5, FOA5, Fom004, NRRL 36425, NRRL 26988, NRRL 26222, NRRL 36311 and Fo47) were tested using the same protocol as before, except the final spore concentrations were 2 x 10^4 spores / ml.

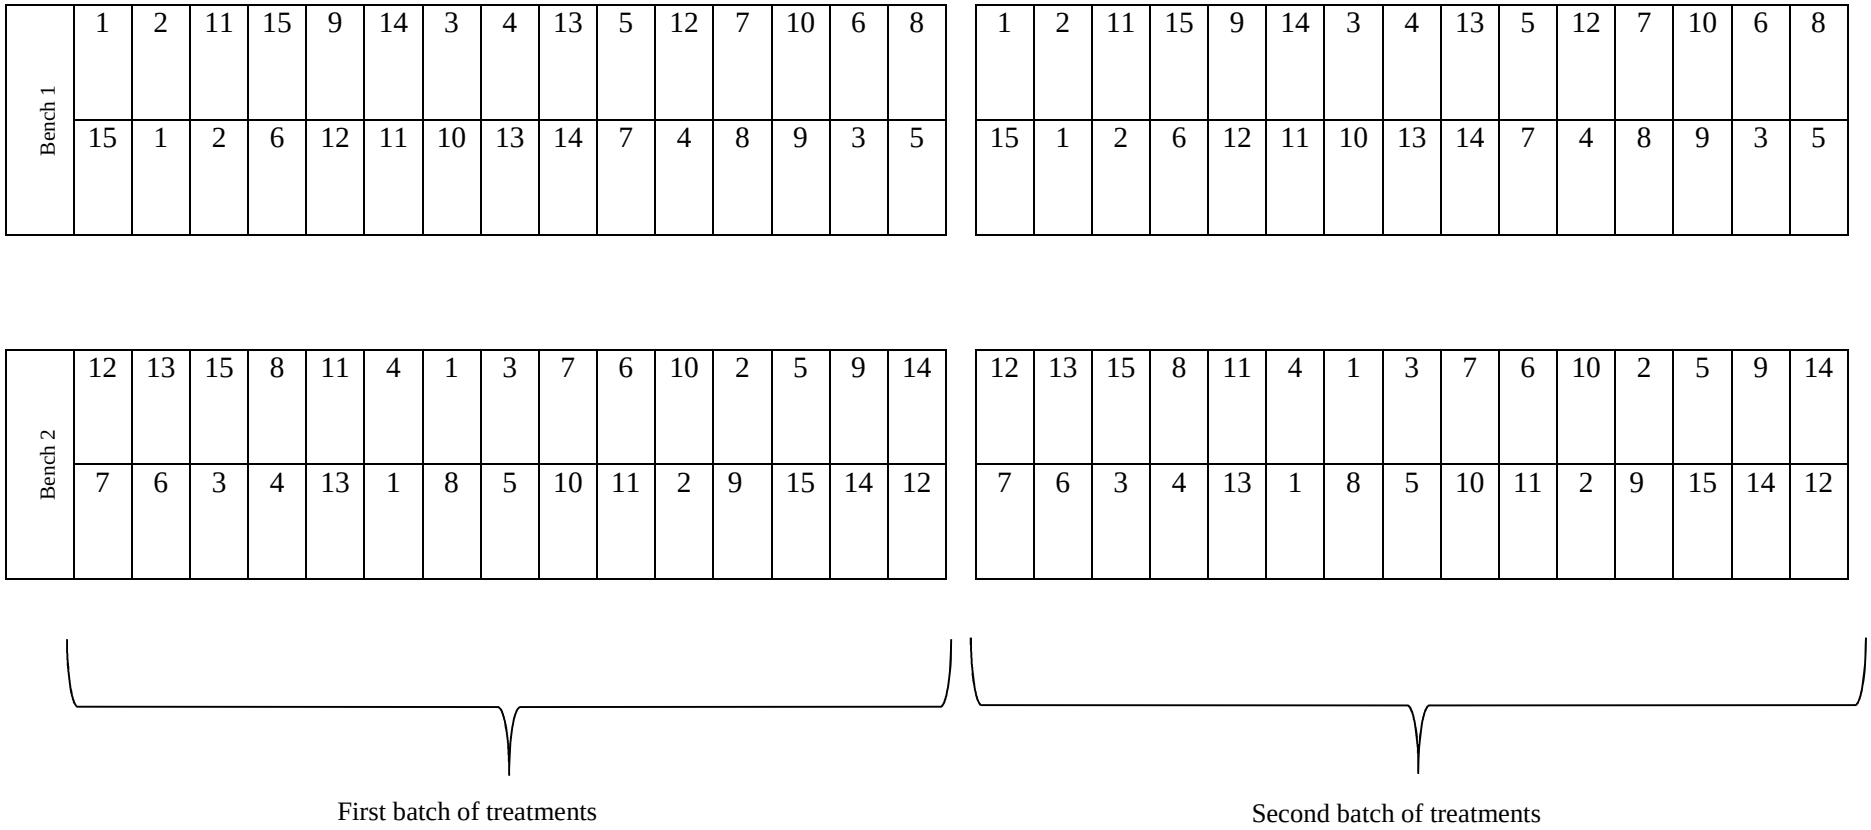

Figure 14. Seedling assay for determining levels of *Fusarium* pathogenicity (randomised block design). 15 treatments were tested and each treatment was repeated four times. Each square represents a 4x7 well-seedling tray. One seed was planted into each well (*i. e.* 28 seeds per treatment).

Table 7. Host and species level distribution of *Fusarium* isolates (74) used in onion seedling assay. Forty *F. oxysporum* isolates (**in bold**) were chosen for characterisation based on housekeeping genes, microsatellite markers and effectors.

3.3.3 Characterisation of *F. oxysporum* isolates from diseased *Allium* species and other formae speciales using housekeeping genes

Sequences for calmodulin, B-tubulin and RNA polymerase II subunit (*RPB2*) were generated in order to characterise 40 *F. oxysporum* isolates from diseased *Allium* species with reference to representatives of ff. spp. *cepae, lycopersici, freesia, pisi, medicaginis, asparagi, gladioli* and *dianthi* (Table 7). The primers used (T1/T22, CL1/CL2A, 5F2/7cR/7cF/11aR) were identical to those used in previous studies (Table 8; O'Donnell *et al*. 1998a, 2000, 2007; O'Donnell and Cigelnik, 1997). Thermal cycling conditions were as in the relevant publications. All PCR reactions, sequencing and sequence editing were prepared as described in Section 2.3.1.2.

Additionally, the identity of eleven *F. oxysporum* isolates requested from culture collections based on their *TEF* sequence similarity and ability to cause disease in the onion seedling bioassay, representing ff. spp. *lycopersici, freesia, pisi, freesia, medicaginis, lycopersici, asparagi, asparagi, gladioli, dianthi* and biocontrol agent Fo47 were confirmed based on *TEF* sequencing as in Section 2.3.1.2.

Table 8. Sequences, target gene, and origin of primers used for the characterisation of *Fusarium oxysporum* isolates from diseased onions and representatives of several formae speciales.

3.3.4 Characterisation of *F. oxysporum* isolates from diseased *Allium* species and other formae speciales using microsatellite markers

Ten previously published microsatellite markers for *F. oxysporum* were tested to determine the intraspecific variation within 40 *F. oxysporum* isolates from diseased *Allium* species and ff. spp. *cepae, lycopersici, freesia, pisi, medicaginis, asparagi, gladioli* and *dianthi* (Table 7; Bogale *et al*., 2005, 2: Almany *et al*., 2009).

DNA of 40 *F. oxysporum* isolates was extracted by using DNeasy Mini protocol (Qiagen) with minor modifications. Freeze-dried material (20 mg) was placed in a 2 ml screw-cap tube and a FastPrep instrument (MPBio) was used for trituration at 6.0 m/s for 40 seconds. Extraction was continued by proceeding to step 7 of the protocol.

Initially, ten unlabelled microsatellite primer pairs (Table 9) were tested on five *F. oxysporum* isolates representing ff. spp. *lycopersici* (FOLR1), *cepae* (Fus2 and D2) and two non-aggressive isolates from diseased onion (Fus1 and 151). Individual PCRs (10 µl) consisted of 5 µl of RedTaq (Sigma-Aldrich), 3 µl of sterile water and 0.5 µl each of the 20 µM forward/reverse primers. PCR conditions were as follows: initial denaturation for 4 minutes at 94°C, followed by 35 cycles of 30 seconds denaturation at 94°C, annealing for 30 seconds, individual annealing temperatures are in Table 9, and extension for 30 seconds at 72°C. The program ended with a 10 minutes final extension at 72°C. Polymorphisms between amplicons were evaluated based on 2% agarose gel electrophoresis (see Section 2.3.1.2). The location of primer binding sites (Table 2) was determined based on the *F. oxysporum* f. sp. *lycopersici* 4287 genome sequence by using BLAST search (Broad Institute; Altschul *et al*., 1990).

Following selection of primer pairs which were polymorphic amongst isolates, five labelled forward primer pairs (using four fluorescent labels: NED, VIC,

FAM, PET) were used to analyse 40 *F. oxysporum* isolates from diseased *Allium* species and formae speciales (Table 7). The size of labelled PCR products was determined on an ABI Prism 3100 Genetic Analyser and allele sizes assigned using GeneMarker v. 1.6 (SoftGenetics). Flexibin (Amos *et al*., 2007) was used to bin allele sizes and estimate the relative number of sequence repeats for individual *F. oxysporum* isolates at each of the five loci.

*Based on *Fusarium oxysporum* f. sp. *lycopersici* genome sequence (Broad Institute) ** Ta: Annealing temperature (°C)
1: Bogale *et al*., 2005, 2: Almany *et al*., 2009 *** NED, VIC, FAM, PET: fluorescent labels

Microsatellite primers were also tested in two sets of multiplex PCRs in an attempt to make the analysis more time- and cost-effective. The M1 PCR reaction comprised FOL15, FOL 245, MB 2 and MB 17 primer pairs, while the M2 reaction contained CH2-15, FOL 35, FO 356 and FOL 680 primer pairs.

3.3.5 Development of microsatellite markers on mobile pathogenicity chromosomes to characterise *F. oxysporum* isolates from diseased *Allium* species and other formae speciales

In order to further characterise the 40 *F. oxysporum* isolates, microsatellite markers identified on a *SIX* gene encoding mobile pathogenicity chromosome (MPC) of *F. oxysporum* f. sp. *lycopersici* were tested (Ma *et al*., 2010; Broad Institute). Contigs corresponding to chromosome 14 (MPC) of *F. oxysporum* f. sp. *lycopersici* were utilized to identify microsatellite-coding sequences by using the Perfect Microsatellite Repeat Finder (Ammar, 2006). Sequences encoding short sequence repeats (SSRs) were annotated by using Blast search on NCBI database to discard those sequences encoding genes and transposable elements (NCBI; Altschul *et al*., 1990). Twelve loci were chosen for further analysis and specific primer pairs were designed by Primer3 (Rozen and Skaletsky, 2000; for primer sequences see Results).

Initially, twelve unlabelled microsatellite primer pairs (for primer sequences see Results) were tested on five *F. oxysporum* isolates representing formae speciales *lycopersici* (FOLR1), *cepae* (Fus2 and D2) and two non-aggressive isolates from diseased onion (Fus1 and 151). Individual PCRs (10 µl) consisted of 5 µl of RedTaq (Sigma-Aldrich), 3 µl of sterile water and 0.5 µl each of the 20 µM forward/reverse primers. PCR conditions were as in Section 3.3.4 with annealing temperature at 55°C. Microsatellite markers were evaluated based on 2% agarose gel electrophoresis. A single primer pair (21384F and 21384R) showed variation and resulted in a PCR product for all five *F. oxysporum* isolates. The labelled forward primer (using fluorescent label: PET) then was used to analyse 41 *F. oxysporum* isolates from diseased *Allium* species and formae speciales (Table 7). Labelled PCR products were multiplexed; Mix1: 38459, 21384 and MB2, Mix2: FOL680, FOL356, FOL35 and FOL245. The size of labelled PCR products was determined, allele sizes

and relative number of sequence repeats for individual *F. oxysporum* isolates was estimated as in 3.3.4.

3.3.6 Screening of published effector genes in *F. oxysporum* isolates collected from alliums and other host species

F. oxysporum isolates associated with diseased onion (Fus2 and A28) along with representatives of ff. spp. *lycopersici* (FOL2), *medicaginis* (Fom004) and *asparagi* (FOA5) were initially screened for the presence of a set of six effector genes; *SIX6, SIX7, FTF1, ORX1, PEP1* and *PEP2* originally used to screen *F. oxysporum* ff. spp. *lycopersici, phaseoli, cubense* and *vasinfectum*, respectively (Lievens *et al*., 2009a; Meldrum *et al*., 2012; Ramos *et al*., 2007; Chakrabarti *et al*., 2011). *F. oxysporum* f. sp. *cepae* had not been screened previously for the presence of any of these effectors. Seven published primer pairs (Table 10) were tested on this small set of isolates using the following thermal cycling conditions: initial denaturation for 1.5 minute at 94°C, followed by 35 cycles of 30 seconds denaturation at 94°C, annealing for 1.5 minutes at the 55°C and extension for 2 minutes at 68°C. The program ended with a 10 minutes final extension at 68°C. *SIX7* products successfully amplified from *F. oxysporum* isolates were sequenced. PCR reactions, sequencing and sequence editing were carried out as described in Section 2.3.1.2.

F. oxysporum isolates (175) obtained from diseased *Allium* species were screened for the presence of the *SIX7* gene using a primer pair designed by Lievens *et al*. (2009; Appendix I). Additionally 26 representatives of other ff. spp. *cepae, lycopersici* races 1 and 2, *narcissi, gladioli, asparagi, medicaginis, tulipae, dianthi, cubense, phaseoli, pisi* races 1, 2 and 5, *freesia* and biocontrol agent Fo47 were included in the *SIX7* screening.

Isolates which tested negative for the presence of *SIX7* by using the primer pair published by Lievens *et al*. (2009) were screened using newly designed *SIX7* primer pairs to confirm absence of this gene in *F. oxysporum* isolates from diseased onion (for primer sequences see Results). Primer pairs were manually designed based on alignment of *SIX7* sequences from *F. oxysporum* ff. spp. *cepae, lycopersici, lilii, narcissi, pisi* and *gladioli*. Two primer pairs were designed on the conserved regions of *SIX7*, while *F. oxysporum* f. sp. *cepae*-specific primers were designed on the variable regions. Primers were tested in combinations on nine *F. oxysporum* isolates from diseased *Allium* hosts (Fus2, D2, 151, A28, Fus1, A13, and Gr4), formae speciales *lycopersici* (FOLR1) and *medicaginis* (Fom004). PCR reactions were set up as described in Section 2.3.1.2.

F or f: forward primer, R or r: reverse primer

PCR cycling conditions were as follows: initial denaturation for 5 minutes at 95°C, followed by 40 cycles of 1 minute denaturation at 93°C, annealing for 1 minute at the 56°C and extension for 1 minute at 72°C. The program ended with a 10 minutes final extension at 72°C.

3.3.7 Cloning of the homologous *SIX7* sequence of *F. oxysporum* f. sp. *cepae*

To confirm that the homologous *SIX7* sequence of *F. oxysporum* f. sp. *cepae* was not an artefact of incorrect sequencing, the *SIX7* genes of *F. oxysporum* f. sp. *cepae* (Fus2 isolate) and *F. oxysporum* f. sp. *lycopersici* race 2 (FOL2 isolate) were cloned and sequenced.

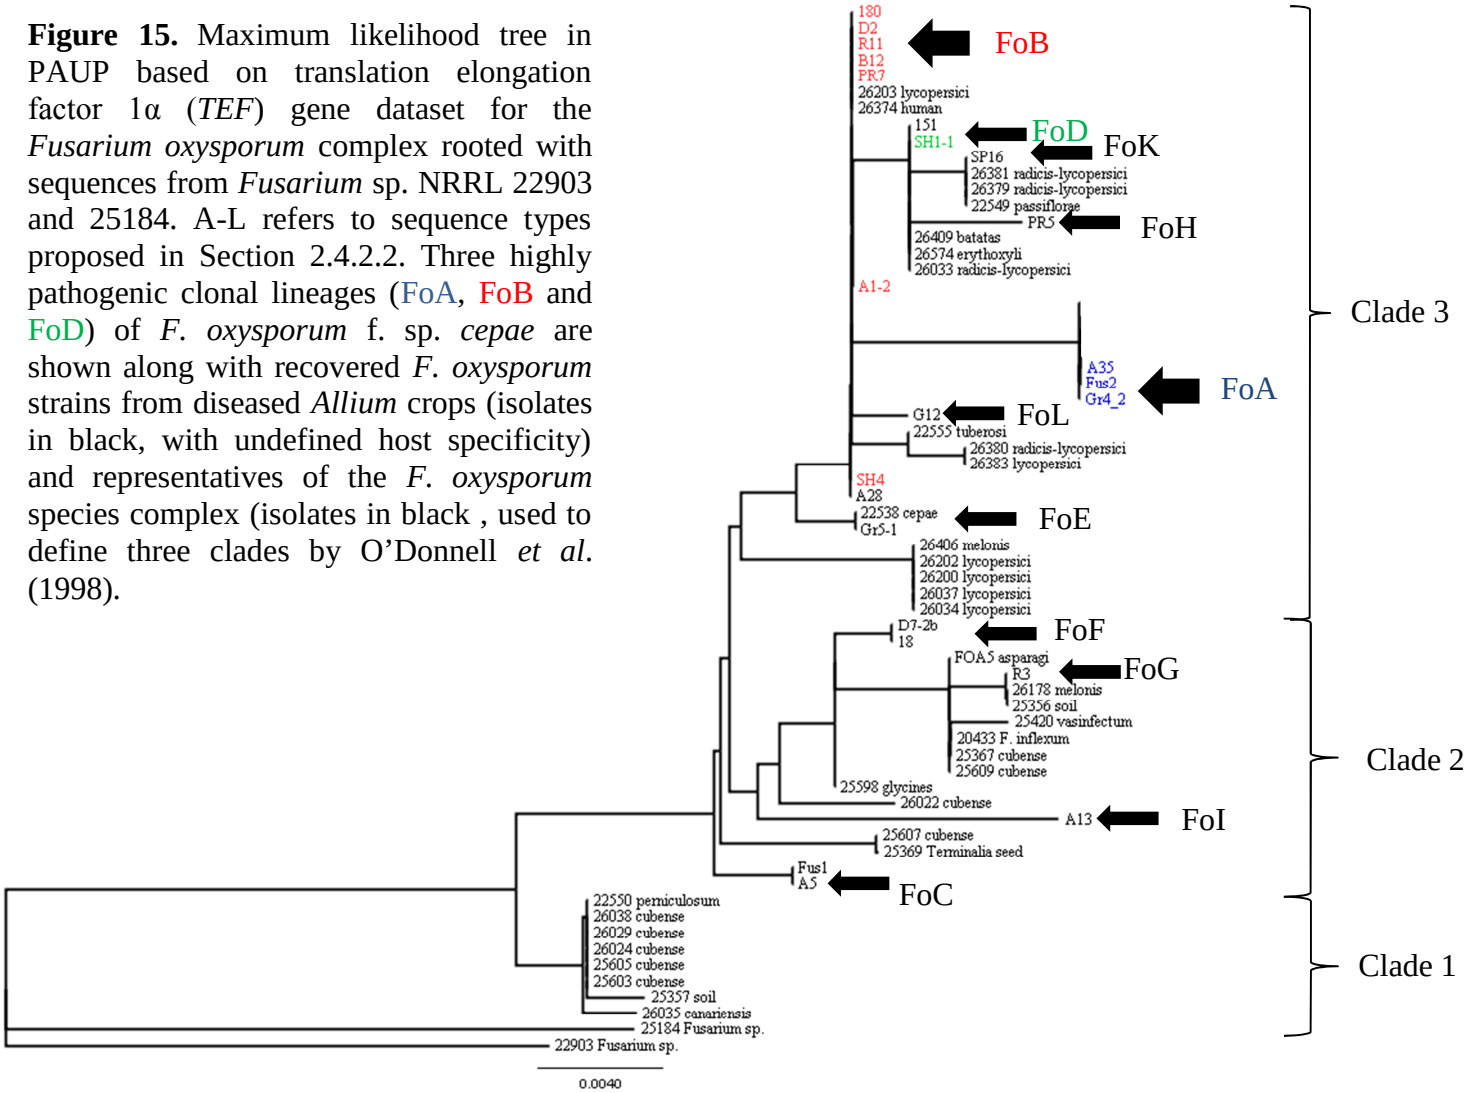
PCR products of Fus2 and FOL2 isolates obtained using SIX7-F1 and SIX7R1 primers (Lievens *et al*., 2009a; Table 7) were cleaned using a Qiagen PCR purification kit following the manufacturer's recommendations. A TOPO® TA cloning kit (Invitrogen) was used to ligate PCR products into pCRII TOPO® vectors. Ligations were carried out at 14°C for 4 hours. Chemical transformation was carried out using TOP10F' chemically competent cells (Invitrogen) following the producers protocol. 20 µl suspension was used each for the inoculation of LB plates containing ampicillin (100 µg/ml) to select *SIX7*-amplicon-containing white *E. coli* cells (Sambrook *et al*., 1989). Ten white colonies were sub-cultured each into 2ml tubes containing LB medium amended with ampicillin (100 µg/ml) and grown for 24 hours at 37°C. Plasmid DNA was then isolated using a QIAprep Spin Miniprep Kit (Qiagen). Positive transformants were identified by PCR using M13 forward and reverse primers targeting pCRII plasmid sequence following Invitrogen's recommendations. Amplicons were purified, sequenced and analysed as in 2.3.1.2.

3.4 RESULTS

3.4.1 Cladistic analysis of *F. oxysporum* isolates associated with diseased *Allium* species and different formae speciales based on *TEF* sequences

A maximum likelihood tree was constructed in PAUP using *TEF* to study the genetic organisation of FOC within the *F. oxysporum* species complex (Figure 15). Sequences (28) of *F. oxysporum* isolated from diseased *Allium* crops representing eleven *TEF* sequence types (FoA-FoL, see Chapter 2) were used in conjunction with the *TEF* dataset generated by O'Donnell *et al*. (1998a; Figure 1) to study the genealogies of isolates associated with diseased *Allium* species. Sequences fell into three clades of the *F. oxysporum* species complex and the topology of the maximum likelihood tree agreed with a parsimonious tree published by O'Donnell *et al*. (1998a, Figure 1). Representatives of *TEF* sequence types FoA, FoB, FoD, FoE, FoH, FoK, FoL (Section 2.4.2.2) from diseased onion fell into Clade 3, while isolates belonging to *TEF* sequence types FoC, FoF, FoG and FoI fell into Clade 2. *F. oxysporum* isolates belonging to ST FoB shared the same *TEF* sequence with a *F. oxysporum* f. sp. *lycopersici* and a human pathogen isolate. Similarly, FoD (*batatas, erythoxyli, radicis-lycopersici*), FoK (*radicis-lycopersici* and *passiflorae*) and FoG (*melonis* and soil isolate) were found polyphyletic.

Figure 15. Maximum likelihood tree in PAUP based on translation elongation factor 1α (*TEF*) gene dataset for the *Fusarium oxysporum* complex rooted with sequences from *Fusarium* sp. NRRL 22903 and 25184. A-L refers to sequence types proposed in Section 2.4.2.2. Three highly pathogenic clonal lineages (FoA, FoB and FoD) of *F. oxysporum* f. sp. *cepae* are shown along with recovered *F. oxysporum* strains from diseased *Allium* crops (isolates in black, with undefined host specificity) and representatives of the *F. oxysporum* species complex (isolates in black , used to define three clades by O'Donnell *et al.* (1998).



Sequences of 32 *F. oxysporum* isolates associated with *Allium* species representing TEF STs FoA – FoM) were compared with the *TEF* sequences of 100 isolates (from GenBank) representing 39 different formae speciales using neighbour-joining method (Figure 16). The *TEF* sequences formed three clades and the distribution of *TEF* sequence types agreed with the maximum likelihood tree (Figure 15). The diversity of isolates from *Allium* species indicates the polyphyletic origin of FOC. Moreover, more than one formae speciales occurred in each clonal lineage (Figure 16). For example, clonal lineage FoA comprises identical *TEF* sequences of cultures pathogenic to *Allium* species, tomato (*Solanum lycopersicum*), peas (*Pisum sativum*), freesia (*Freesia* sp.), alfalfa (*Medicago sativa*) and asparagus (*Asparagus officinalis*). The same trend can be seen in clonal lineage FoB, representatives of formae speciales *cepae, lycopersici, batatas* along with a human pathogenic strain share identical *TEF* sequences. Further examples are in clonal lineage FoD which consists of representatives of ff. spp. *cepae, niveum, bouvardiae* and *chrysanthemi*, FoE (*chrysanthemi, tulipae, vasinfectum, dianthi* and *gladioli*), FoI (*pisi*), FoF (*lilii*), FoC (*gladioli*) and FoG (*melonis, lini, dianthi* and *cucumerinum*).

The results suggested that *F. oxysporum* f. sp. *cepae* (FOC) and isolates belonging to other formae speciales can have identical *TEF* sequence (Figure 15 and Figure 16). Five *F. oxysporum* isolates were requested from culture collections based on similarity to *TEF* sequence type FoA (NRRL22544 - *lycopersici*, NRRL26990 – *freesia*, NRRL36311 – *pisi*, FOA4 – *asparagi* and Fom004 – *medicaginis*). Five additional *F. oxysporum* isolates were requested based on symptoms caused by them (NRRL26993 – *gladioli*, NRRL26988 – *freesia*, NRRL36425 – *lycopersici*, FOA5 – *asparagi* and NRRL26222 – *dianthi*).

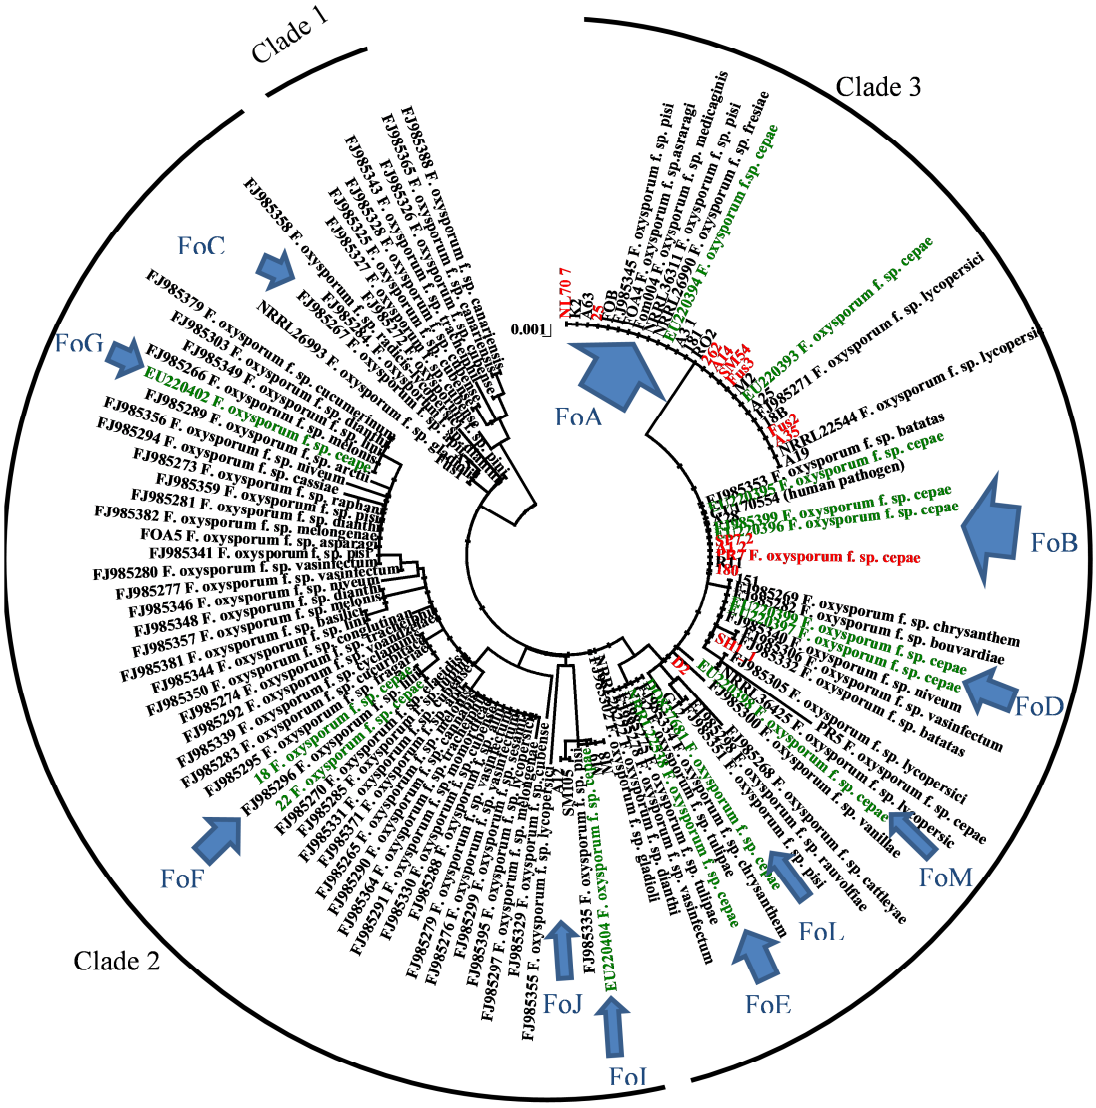


Figure 16. Cladogram of representatives of *Fusarium oxysporum* formae speciales based on *TEF*. Consensus tree is shown with bootstrap values from 1000 replications. GenBank accession number is indicated for each reference sequence. Isolates from diseased *Allium* species are shown in red. Sequences of *Fusarium oxysporum* f. sp. *cepae* isolates published by various groups are in green. FoA - FoM refer to sequence types (STs) proposed in chapter 2 which can also be seen as clonal lineages. Moreover, the three clades of the *F. oxysporum* species complex proposed by O'Donnell *et al*. (1998a) are shown.

SUMMARY

TEF sequence of *F. oxysporum* isolates from diseased *Allium* crops were analysed by neighbour-joining and maximum likelihood methods and isolates formed two main clades, Clade 2 and Clade 3 having been determined by O'Donnell *et al*. (1998a). The diversity of isolates from *Allium* species indicated the polyphyletic origin of FOC. Moreover, more than one formae speciales occurred in each clonal lineage; FOC and isolates belonging to other formae speciales can share identical *TEF* sequence. For example, the most commonly occurring ST FoA (78%) comprises identical *TEF* sequences of cultures pathogenic to *Allium* species, tomato, freesia, peas and alfalfa.

To clarify that these findings were robust, various molecular markers such as three housekeeping genes (RPB2, calmodulin and β-tubulin), six microsatellite markers and effector gene (*SIX7*) as well as pathogenicity on onion seedlings (see next Section) were tested on 40 *F. oxysporum* isolates recovered from diseased *Allium* species and representing several sequence types. Additionally, representatives of other formae speciales grouped together with clonal lineages of FOC were included in these experiments.

3.4.2 Onion seedling assay using *Fusarium* isolates from diseased *Allium* species and different formae speciales

Disease symptoms appeared as pre- and post-emergence damping-off four weeks after inoculation and as the disease progressed onion leaves became wilted and yellow (Figure 17). In some cases, white/pink mycelium was observed on the surface of the necrotic onion leaves. Untreated plants remained symptomless. The survival index (angular transformed percentage survival) was calculated of each treatment. The REML analysis showed that there was a significant difference ($P \leq$

0.001) between treatments (Table 11, Appendix IV). The final survival index was 12.1 for the very aggressive Fus2 isolate (positive standard), 38.3 for the biocontrol agent Fo47 strain (negative standard) and 57.5 for the untreated. These treatments were significantly different from each other as the least significant difference was 11.4. Continuous variation was found among the 74 *Fusarium* isolates tested (Figure 18).

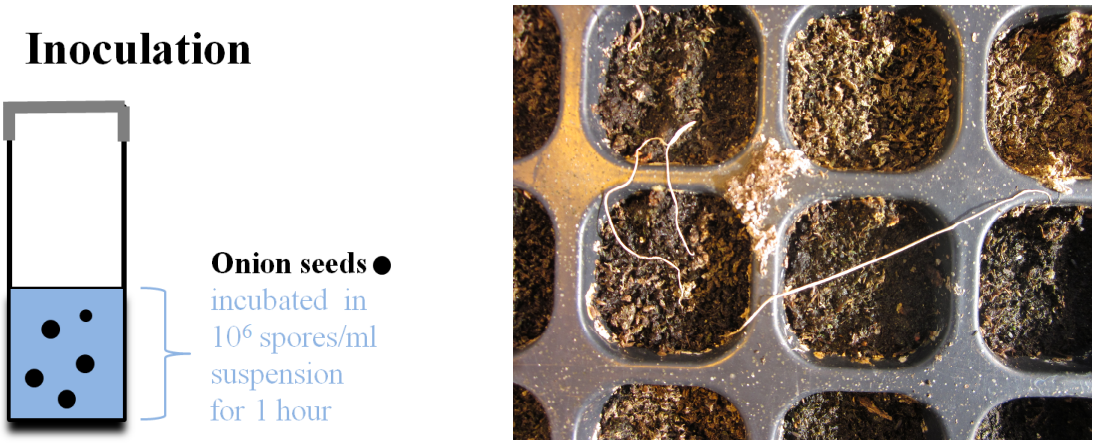

Figure 17. Inoculation method and damping-off symptoms of onion seedlings four weeks after sowing inoculated onion seeds.

Isolates with survival index not significantly different (overall maximum l.s.d 5%: 11.4) from the isolate Fus2 according to the REML analysis were considered very aggressive. Isolates with survival index significantly different from Fo47 treatment according to the REML analysis were considered as aggressive. Isolates with survival index not significantly different from Fo47 treatment and untreated controls were considered non-aggressive.

F. oxysporum isolates from diseased *Allium* species

Based on the seedling assay, 20 isolates out of 42 *F. oxysporum* isolates from diseased *Allium* species were very aggressive, three moderately aggressive while the remaining 19 isolates were found non-aggressive (Table 11, Figure 18). The very aggressive *F. oxysporum* isolates all originated from onion except for one from leek (PR7) and one from shallot (SH1-1) and originated from the UK, the Netherlands, Spain, USA and Chile, respectively. Non-aggressive strains were from onion, leek, shallot, garlic and Welsh onion grown in the UK, the Netherlands, Italy, Japan, Spain, Germany and Australia. However, three *F. oxysporum* isolates (NRRL 22538, 22, 18) defined as non-aggressive based on the seedling assay were originally identified as FOC in previous studies (Dissanayake *et al*, 2009ab, Agricultural Research Service, ARS).

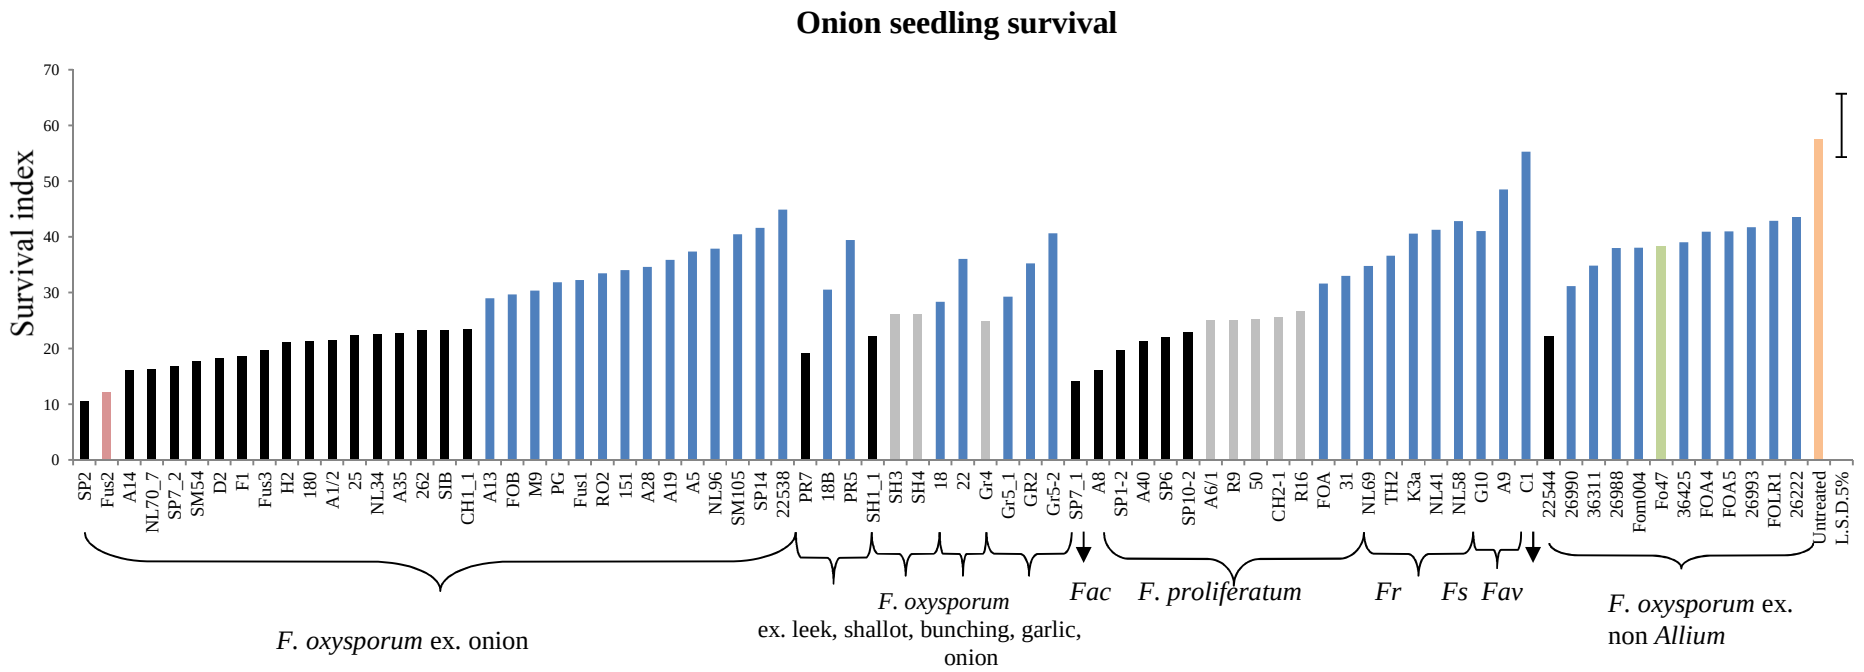

Figure 18. Survival index (angular transformed percentage onion seedling survival) of 74 *Fusarium* isolates representing isolates from diseased *Allium* species and eight formae speciales.

Blue isolates were not significantly different (l.s.d 5%) from **Fo47 treatment** and not significantly different (l.s.d 5%) from **Untreated** according to REML analysis (Di of Untreated was 57.54)
***overall maximum l.s.d. 5%**: approximate least significant differences (5% level) of REML means
TEF: translation elongation factor (*TEF*) sequence types defined in Chapter 2, (see Appendix II-III)

F. oxysporum isolates representing different formae speciales

Eleven *F. oxysporum* isolates representing seven formae speciales *lycopersici, freesia, pisi, asparagi, medicaginis, gladioli* and *dianthi* and biocontrol strain Fo47 (negative standard) were tested on onion seedlings (Table 11, Figure 18). Nine out of ten treatments (isolates) were also not significantly different from the negative standard (Fo47) treatment. Interestingly, isolate NRRL 22544 was not significantly different from the positive standard (Fus2) treatment although it was originally identified as f. sp. *lycopersici*.

Other *Fusarium* species

Five *F. proliferatum* isolates from the UK and Spain (A8, A40, SP1-2, SP6 and SP10-2) were found very aggressive and four from British, Spanish and American onions were moderately aggressive. Two *F. proliferatum* (FOA and 31), two *F. solani* (G10 and A9), five *F. redolens* (NL69, TH2, K3a, NL41 and NL58) and one *F. avenaceum* (C1) isolate tested were non-aggressive in onion seedlings. One *F. acuminatum* isolate (SP7-1) was very aggressive.

Additionally, 14 *F. oxysporum* isolates from diseased *Allium* species and formae speciales *asparagi, lycopersici, medicaginis, pisi, freesia* and a biocontrol strain (Fus2, 180, D2, NL96, A13, Fus1, A5, FOA5, Fom004, NRRL 36425, NRRL 26988, NRRL 26222, NRRL 36311 and Fo47) were tested using the same protocol as before, except the final concentrations were fifty times less (2×10^4 spores/ml) than in the inoculum dose in the original protocol (10^6 spores/ml, Appendix IV). All isolates were less aggressive at this lower dose. No significant difference was observed between untreated (water immersed) and treatments with twelve isolates (NL96, A13, Fus1, A5, FOA5, Fom004, NRRL 36425, NRRL 26988, NRRL 26222,

NRRL 36311 and Fo47), which were therefore considered to be non–pathogenic in seedlings of standard susceptible cultivars of onion. In the same experiment, two isolates (D2 and 180) isolates were as aggressive in onion seedlings as the standard pathogenic isolate Fus2.

Combining the the *TEF* sequence data with the results of the pathogenicity assays showed most clades or sequence types did not correlate with pathogenic ability on onion (Table 11). There are three exceptions: sequence types FoC, FoI and FoJ were found non-aggressive in onion seedlings (although only one or two isolates were chosen from each of these STs).

SUMMARY

In total, 63 *Fusarium* isolates associated with basal rot of *Allium* species and 11 isolates associated with other hosts were tested in a rapid seedling assay to define their aggressiveness in onion seedlings. *F. oxysporum* isolates associated with onion basal rot (42) belong to at least nine different *TEF* sequence types (STs FoA-FoL). However, *F. oxysporum* isolates from *Allium* species that tested strongly or moderately aggressive in onion seedlings (termed as FOC) were found only in three STs (FoA, FoB and FoD). Five *F. proliferatum* and one *F. acuminatum* isolate tested were very aggressive. Additionally, four *F. proliferatum* isolates were moderately aggressive, while two *F. proliferatum*, two *F. solani*, five *F. redolens* and one *F. avenaceum* isolate tested were non-aggressive in onion seedlings. Interestingly, a *F. oxysporum* isolate (NRRL 22544) was not significantly different from the positive standard (Fus2) treatment although it was originally identified as f. sp. *lycopersici*.

3.4.3 Molecular characterisation of *F. oxysporum* isolates using housekeeping genes

Three housekeeping genes (calmodulin, B-tubulin and *RPB2*) were used for the characterisation of 40 *F. oxysporum* strains representing formae speciales *cepae, lycopersici, pisi, medicaginis, asparagi, freesia, dianthi, gladioli* along with non-aggressive isolates recovered from diseased *Allium* species and biocontrol strain Fo47 (Table 12). Additionally *TEF* sequences of these isolates were also included in this analysis as it is a housekeeping gene. Isolates were divided into sequence types (STs) based on the individual and combined datasets. *TEF* (14 STs) and *RPB2* (13 STs) were more informative compared to calmodulin (7 STs) and β-tubulin (7 STs) (Table 12). The combination of the four datasets led to the identification of 19 STs among the 40 *Fusarium oxysporum* isolates analysed (Table 12).

The combined dataset was analysed in relation to host and the results of the onion seedling assay (Figure19A). Several sequence types were exclusively found from onion (ST6, ST7, ST9, ST10, ST13 and ST19), carnation (ST18), freesia (ST15), tomato (ST16), asparagus (ST17), garlic (ST8), bunching onion (ST11), leek (ST12) and the biocontrol strain (ST14). On the other hand, a few sequence types were found among various formae speciales e.g. ST1 comprised formae speciales *cepae*, *lycopersici* and *asparagi* isolates; ST2 formae speciales *cepae, medicaginis* and *pisi*; ST3 included isolates from onion, leek and freesia and ST5 consisted of formae speciales *cepae* and *gladioli* isolates.

Table 12. Multilocus sequence type for 40 *Fusarium oxysporum* isolates from various host plants with reference to survival index, based on *TEF*, *RPB2*, tubulin (*TUB*), calmodulin (*CAL*) and combined sequence types (STs).

TEF: translation elongation factor, CAL: calmodulin, TUB: β-tubulin, RPB2: RNA polymerase II 2nd largest subunit

Survival index: percentage onion seedling survival (angular transformed data)

Black isolates were not significantly different (maximum overall l.s.d 5%: 11.393) from **Fus2 treatment** according to REML analysis; **Grey isolates** were significantly different (l.s.d 5%) from **Fo47 treatment** according to REML analysis; **Blue isolates** were not significantly different (l.s.d 5%) from **Fo47 treatment** and not significantly different (l.s.d 5%) from **Untreated** according to REML analysis (Di of Untreated was 57.54)

***overall maximum l.s.d. 5%**: approximate least significant differences (5% level) of REML means

** Originally designated as tomato pathogen but was very aggressive in onion seedlings

The combined sequence dataset was analysed in relation to the results of the onion seedling assay (Figure 19, Table 12). For interpretation of results, isolates tested in the pathogenicity assay were divided into two groups: “aggressive” and “non-aggressive” based on statistical similarity to the Fo47 treatment. Although it has to be noted that it is a very arbitrary division considering that *Fusarium* isolates showed continuous variation in terms of aggressiveness in onion seedlings. Thirteen sequence types were exclusively found to be non-aggressive (ST5, ST7, ST9- to ST19), while only two were considered as aggressive in onion seedlings (ST4 and ST8). Four sequence types comprised both aggressive and non-aggressive isolates (ST1, ST2, ST3 and ST6). ST1 comprised isolates from tomato, asparagus and onion and surprisingly the isolate from tomato was found to be very aggressive, while one of the onion isolates and the isolate from asparagus were found non-aggressive (Table 12). ST2 consisted of non-aggressive pea, alfalfa and one onion isolates, whereas the very aggressive isolates were all recovered from onion. ST3 contained isolates from onion, leek and freesia. The leek and freesia isolates were non-aggressive unlike the onion isolate. The shallot isolate was found to be aggressive and the onion isolate was non-aggressive in ST6 (Table 12).

In summary, calmodulin, B-tubulin and *RPB2* are the three additional housekeeping genes used in combination for the characterisation of 40 *F. oxysporum* strains. This led to the identification of 19 sequence types (STs), but only two of them (ST4 and ST8) correlated with aggressiveness in onion seedlings. Overall, *TEF, RPB2,* B-tubulin and calmodulin were not useful for the unambiguous identification of formae speciales.

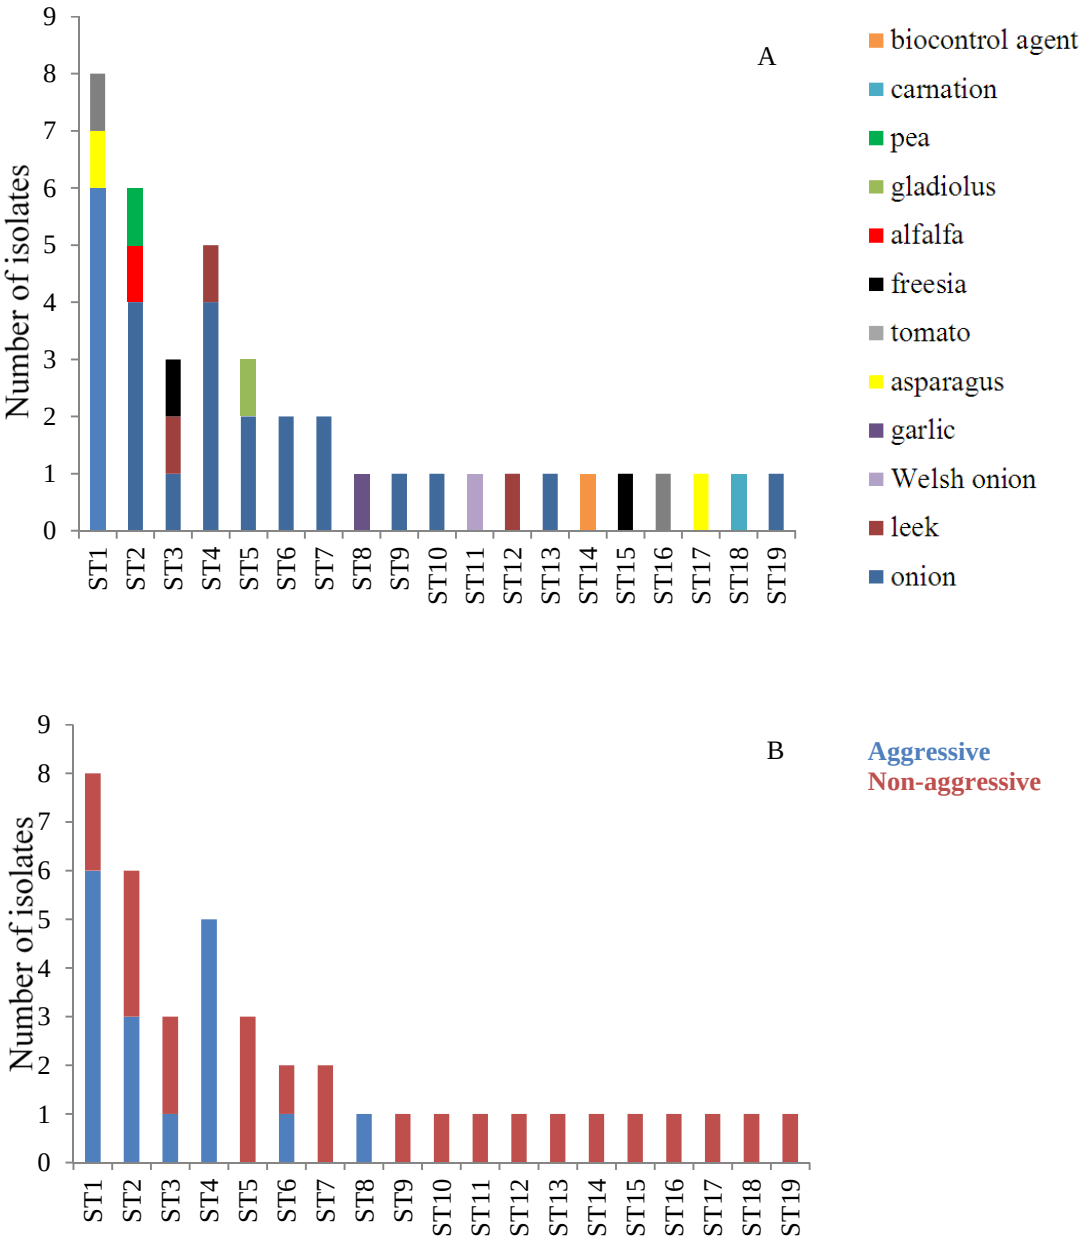

Figure 19. Frequency of sequence types (STs) based on *TEF*, *RPB2*, calmodulin and β-tubulin sequences of 40 *Fusarium oxysporum* isolates from diseased *Allium* and other formae speciales for **A** different host plants and **B** relation to onion seedlings. ST1–ST19: sequence types based on combined dataset of *TEF*, *RPB2*, calmodulin and β-tubulin sequences (see Table 12).

3.4.4 Molecular identification of *F. oxysporum* isolates using published microsatellite markers

Ten previously published (Bogale *et al*., 2005, Almany *et al.*, 2009) microsatellite markers were tested to characterise *F. oxysporum* isolates associated with diseased *Allium* species and different formae speciales.

Ten unlabelled primer pairs amplifying microsatellites were tested on five *F. oxysporum* isolates, representing formae speciales *cepae, lycopersici* and non-aggressive isolates from onion, initially to define the optimal annealing temperatures. The MB 9 primer pair did not give any amplicons and a BLAST search of the MB 9 primer sequences did not give any hits against the *F. oxysporum* genome sequence either. MB13 did not amplify from all isolates. Gel electrophoresis of products suggested that FOL 15, FOL 245, FOL 296, FOL 35 were more informative than FOL296, FOL 680, CH2-15, FOL 356, MB 2, MB 14 and MB 17 (data not shown).

The FOL 245 primer pair did not give a band and MB17 produced a faint band in M1 multiplex PCR and the detection of products of M2 multiplex PCR based on electrophoresis was not informative, therefore primer pairs were used in individual reactions (Figure 20), although, FOL15 and MB2 could be used in a multiplex PCR format.

MB2 (FAM), FOL680 (FAM), FOL356 (VIC), FOL35 (PET) and FOL245 (NED) were chosen for further analysis on the basis of their chromosomal location e.g. each of these markers targeting differing chromosomes.

The 40 *F. oxysporum* isolates (Table 7) from diseased *Allium* species and several different formae speciales were analysed by five microsatellites markers. The fragment lengths varied between MB2: 241-274, FOL680: 193-204, FOL356: 120-326, FOL35: 212-255 and FOL245: 135-267 (Appendix V). Allele size variation of

FOL356 and FOL245 is more likely to be the result of insertion rather than variation in number of microsatellite repeats.

FOL 356 (16 haplotypes), FOL 245(12 haplotypes), MB2 (10 haplotypes) and FOL35 (9 haplotypes) were more informative than, FOL680 (3 haplotypes). In total 26 unique haplotypes were found among 40 *F. oxysporum* isolates from diseased *Allium* species and different formae speciales (Table 13).

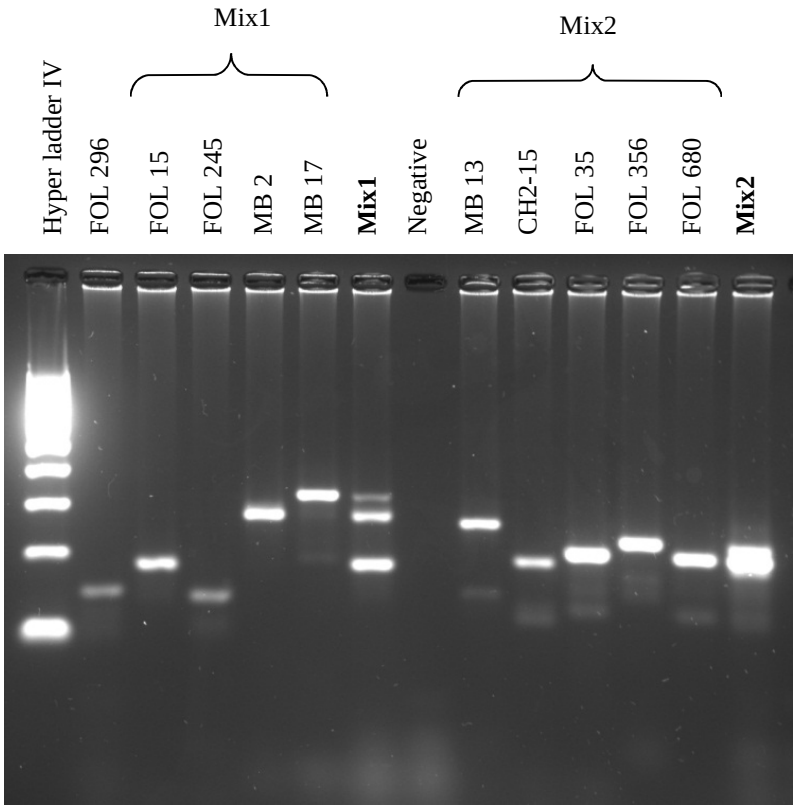

Figure 20. Gel electrophoresis photo of two multiplex microsatellite PCRs in comparison to individual PCRs. Microsatellite primers individually (FOL 15, FOL 245, FOL 296, FOL 35, FOL296, FOL 680, CH2-15, FOL 356, MB 2, MB 14 and MB 17) and in multiplex format (M1 and M2) using Fus2 isolate as template.

Microsatellites used: MB2, FOL680, FOL356, FOL35 and FOL245 (Bogale *et al*., 2005, Almany *et al.*, 2009)
* Repeat number variation of FOL356 and FOL245 is more likely to be the result of insertion rather than variation in number of microsatellite repeats.
SI: Survival index: percentage onion seedling survival (angular transformed data)
Black isolates were not significantly different (maximum overall l.s.d 5%: 11.4) from **Fus2 treatment** according to REML analysis
Grey isolates were significantly different (l.s.d 5%) from **Fo47 treatment** according to REML analysis
Blue isolates were not significantly different (l.s.d 5%) from **Fo47 treatment** and not significantly different (l.s.d 5%) from **Untreated** according to REML analysis (Di of Untreated was 57.54)
***overall maximum l.s.d. 5%**: approximate least significant differences (5% level) of REML means

The combined dataset was analysed in relation to host plants and results of the onion seedling assay (Figure 21). Eleven microsatellite haplotypes were exclusively found from onion (HT3, HT4, HT5, HT6, HT9, HT10, HT14, HT15, HT18, HT20 and HT21), carnation (HT2), freesia (HT1 and HT17), tomato (HT23), asparagus (ST16 and HT25), bunching onion (HT17), leek (HT8 and HT22), peas (HT24) and the biocontrol strain (HT12). On the other hand, a few sequence types were found in different formae speciales such as HT26 comprised formae speciales *cepae* and *gladiolus* isolates, HT13 included isolates from onion, garlic and tomato and HT19 consisted of isolates recovered from onion and garlic. The combined microsatellite dataset was analysed in relation to the results of onion seedling assay (Figure 21, Table 13). As previously, for interpretation of results isolates tested in the seedling assay were divided into arbitrary groups aggressive and non-aggressive based on statistical similarity to the Fo47 treatment.

Isolates representing 19 microsatellite haplotypes were exclusively found to be non-aggressive (HT1- to HT9, HT11, TH12, HT15- to TH17 and TH22- to HT26), while only four were considered as aggressive towards on onion (HT14, HT20, HT21 and HT22). Three haplotypes comprised both aggressive and non-aggressive isolates (HT10, HT13 and HT18). HT13 comprised isolates from tomato, garlic and onion and surprisingly the isolate from tomato was found to be aggressive, while one of the onion isolates was non-aggressive (Table 13). HT10 consisted of one non-aggressive and two aggressive onion isolates. HT18 contained an aggressive leek and a non-aggressive onion isolates (Table 13).

In summary, five published microsatellite markers were tested on the same set of isolates (40) as by housekeeping genes, and this led to the identification of 26

haplotypes (HTs). Unfortunately, only some of the microsatellite patterns could be linked to the pathogenicity e.g. HT14, HT20, HT21 and HT22.

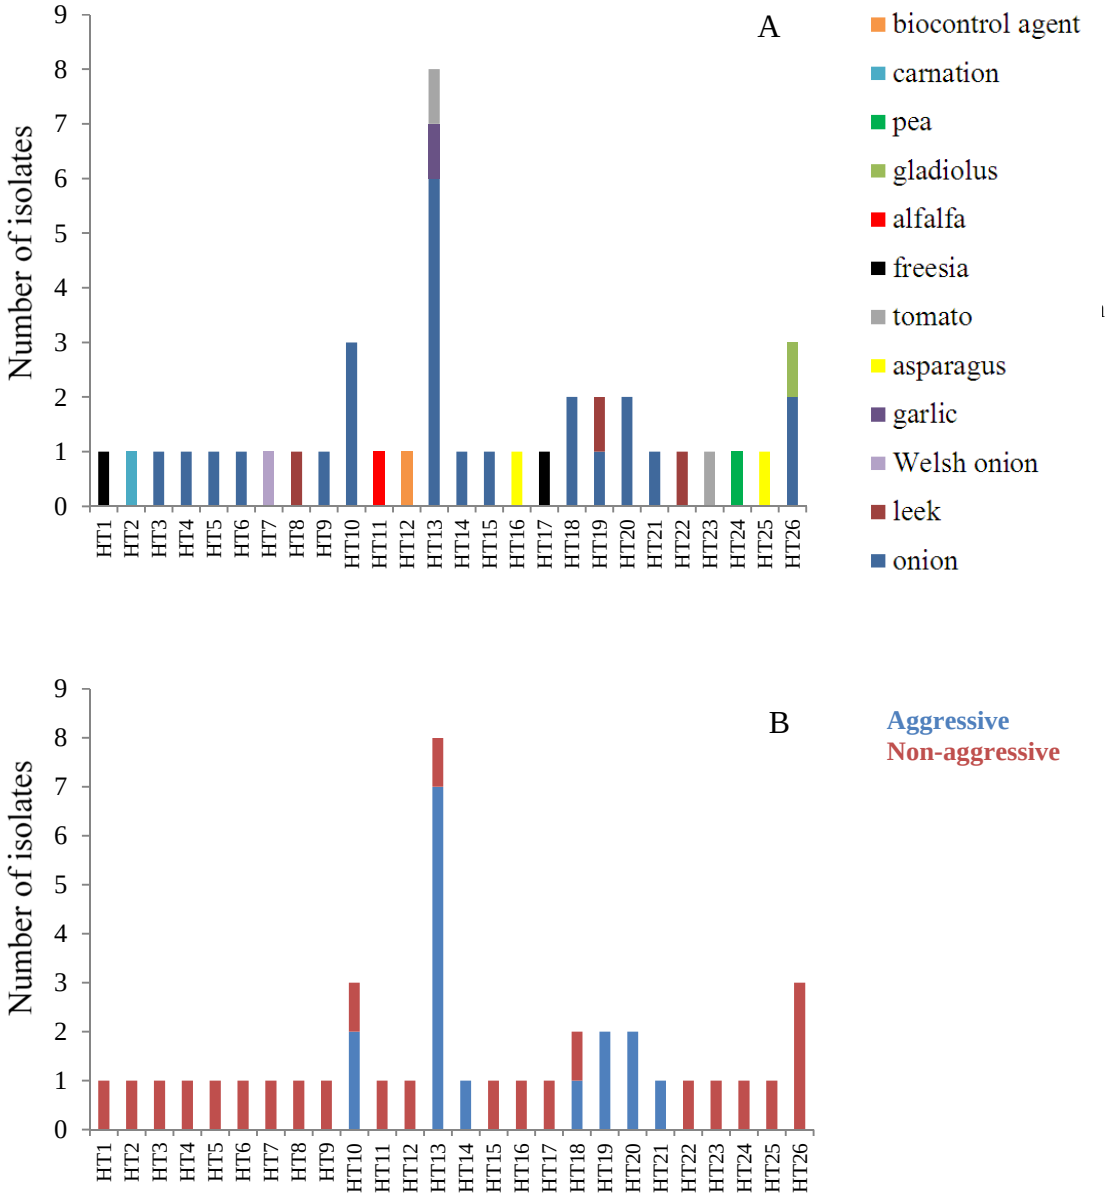

Figure 21. Frequency of microsatellite haplotypes (HTs) based on five published microsatellite markers (MB2, FOL680, FOL356, FOL35 and FOL245; Bogale *et al.*, 2005, Almany *et al.*, 2009) of 40 *Fusarium oxysporum* isolates from diseased *Allium* and other formae speciales for **A** different host plants and **B** relation to onion seedlings.

3.4.5 Development of microsatellite markers on a mobile pathogenicity chromosome of FOL for the characterisation of *F. oxysporum* isolates from diseased *Allium* species and different formae speciales

New microsatellite markers were developed and tested on a *SIX* gene encoding mobile pathogenicity chromosome (chromosome 14) of *F. oxysporum* f. sp. *lycopersici* (Ma *et al*., 2010; Broad Institute) to determine intraspecific variation within *F. oxysporum*.

Twelve loci were chosen for analysis and designed primers (Table 14) were initially tested on five *F. oxysporum* isolates representing formae speciales *cepae, lycopersici* and non-aggressive isolates to detect markers present in a wider range of formae speciales Only one marker, 21384, gave a single product, whereas the other markers gave no product (marker 2887) or multiple products (markers 20774 and 40094) or did not amplify from all five isolates (markers 8735, 4775, 48170, 10051, 83520, 68248, 38459 and 5465). Marker 21384 was chosen for further analysis, as it gave a product with all five isolates initially tested, although isolate D2 gave a faint band.

F. oxysporum isolates (36) representing several different formae speciales were chosen to be analysed by microsatellite marker 21348. The fragment length for marker 21348 varied between 120-187 bp (Appendix V). Seven isolates (including D2, A28, A5, FOA4, Gr4, NRRL 22538 NRRL 36311 and PR5) gave no product for marker 21384. Twenty-six isolates yielded products for both markers and were divided into haplotype groups (Table 15). Marker 21384 was informative, 11 unique haplotypes were found among 36 isolates, although seven isolates were not assigned into any haplotype groups.

Table 14. Microsatellite primer sequences, simple sequence repeat (SSR) motifs in the respective amplicons, number of repeats and location on chromosome 15 of *Fusarium oxysporum* f. sp. *lycopersici*.

The combined lineage specific microsatellite dataset was analysed in relation to host plants and results of onion seedling assay (Figure 22). Three haplotypes were exclusively found from onion (MPC1, MPC2 and MPC4), Welsh onion (MPC9), freesia (MPC8), carnation (MPC11) and tomato (MPC7). However, identical sequence types were found among various formae speciales. For instance MPC10 comprised formae speciales *cepae* and *lycopersici* isolates, MPC3 included isolates from onion and a biocontrol strain, MPC5 comprised isolates from onion, asparagus

and gladiolus whereas MPC6 consisted of isolates recovered from onion, leek, alfalfa and freesia.

Table 15. Microsatellite haplotypes for 36 *Fusarium oxysporum* isolates affecting various host plants using a single microsatellite marker (21384) designed on a mobile pathogenicity chromosome (MPC) of FOL with reference to survival index (SI), estimated repeat number and haplotypes.

* Repeat number variation of 21384 is more likely to be the result of a deletion rather than variation in number of microsatellite repeats.

SI: survival index: percentage onion seedling survival (angular transformed data)

Black isolates were not significantly different (maximum overall l.s.d 5%: 11.393) from **Fus2 treatment** according to REML analysis

Grey isolates were significantly different (l.s.d 5%) from **Fo47 treatment** according to REML analysis

Blue isolates were not significantly different (l.s.d 5%) from **Fo47 treatment** and not significantly different (l.s.d 5%) from **Untreated** according to REML analysis (Di of Untreated was 57.54)

***overall maximum l.s.d. 5%**: approximate least significant differences (5% level) of REML means

The combined lineage specific microsatellite dataset was analysed in relation to the results of onion seedling assay (Figure 22, Table 15). As described previously, for interpretation, the results of the onion seedling assay were divided into arbitrary groups “aggressive” and “non-aggressive” based on statistical similarity compared to Fo47 treatment. Seven haplotypes were exclusively identified as non-aggressive (MPC1, MPC4, MPC5, MPC7, MPC8, MPC9 and MPC11), while none of the haplotypes were exclusively aggressive. Four haplotypes comprised both aggressive and non-aggressive isolates (MPC2, MPC, MPC6 and MPC10). MPC10 comprised isolates from onion and tomato (as previously mentioned the isolate from tomato was found to be aggressive) while one of the onion isolates was non-aggressive. MPC2 consisted of one non-aggressive and two aggressive onion isolates. MPC6 contained an aggressive onion and non-aggressive freesia, alfalfa and leek isolates. MPC3 comprised a non-aggressive onion isolate and biocontrol agent and two aggressive onion isolates.

In summary, twelve microsatellite markers encoded on a mobile pathogenicity chromosome of *F. oxysporum* f. sp. *lycopersici* (Ma *et al*., 2010; Broad Institute) were chosen for analysis and designed primers. After initial screening, one newly designed microsatellite marker (21384) was chosen for further analysis, which resulted in eleven haplotypes (MPC1-MPC11). Unfortunately, the new primers did not give products with all FOC isolates and none of the microsatellite patterns could be linked to the pathogenicity.

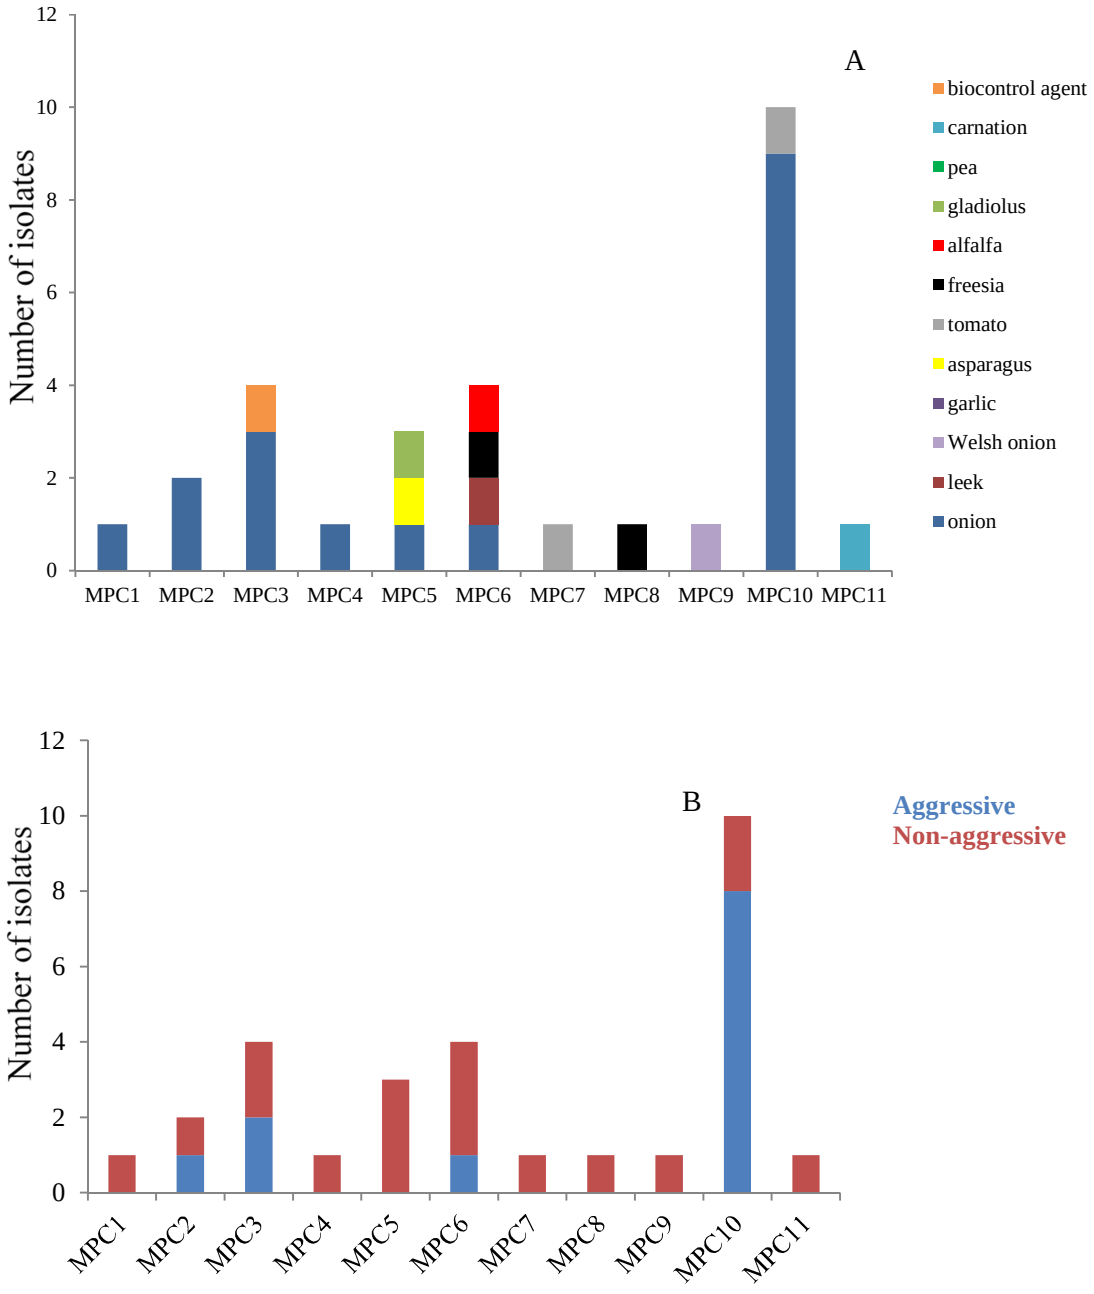

Figure 22. Frequency of microsatellite haplotypes based on a newly developed microsatellite marker (21384) of 36 *Fusarium oxysporum* isolates from diseased *Allium* and other formae speciales for **A** different host plants and **B** relation to onion seedlings.

3.4.6 Screening of published effector genes in *Fusarium oxysporum*

The screening of five *F. oxysporum* (ff. spp. *cepae, medicaginis, lycopersici, asparagi* and non-onion aggressive) isolates for the presence of seven effector genes led to the discovery of a homologue of the *SIX7* gene in the FOC Fus2 isolate. Homologues of six other effector genes were detected in other formae speciales, such as *SIX6* and *OXRED* in f. sp. *lycopersici*, *SIX8* in *lycopersici* and *medicaginis* and *FTF1* in *lycopersici, medicaginis* and *asparagi.*

F. oxysporum isolates (176) from diseased *Allium* crops were screened for the presence of *SIX7* homologue and compared with *TEF* sequence types (see Chapter 2; Appendix II, Figure 23). The homologue of *SIX7* was only present in the majority of isolates with sequence type FoA. Within *TEF* sequence type FoA, nine isolates tested negative and 128 tested positive for the presence of the *SIX7* gene. The nine isolates which tested negative were recovered from Australian leek (1 isolate), British garlic (2 isolates) and British onion (6 isolates).

When *F. oxysporum* isolates (23) representing twelve different formae speciales were also screened for the presence of *SIX7*, it was found in *F. oxysporum* ff. spp. *lycopersici* race1 and 2, *narcissi, gladioli and pisi* race 1 isolates, and was absent in formae speciales *tulipae, asparagi, medicaginis, freesia, dianthi,* and *pisi* race 2 and race 5. The *SIX7* PCR products were sequenced and compared to published reference sequences of formae speciales *lycopersici* and *lilii* (accession numbers: GQ268954 and GQ268960; Figure 24). All FOC isolates containing the *SIX7* homologue shared the same sequence (Figure 24; type SIX7_A). Surprisingly, the *SIX7* sequence of one of the *lycopersici* (NRRL22544) isolate was identical to the *SIX7* sequence of the *cepae* isolates.

Sequences of the other *lycopersici* isolates were identical (type SIX7_C) to the reference (accession number GQ268954). It has to be noted that the "*lycopersici*" isolate NRRL22544 was found to be aggressive in onion seedlings (Table 11). Sequencing of the *SIX7* homologues of formae speciales *narcissi* (type SIX7_B), *gladioli* (type SIX7_E) and *pisi* race 1 (type SIX7_F) isolates and comparison to reference isolates f. sp. *lilii* (type SIX7_D) revealed that there are differences between the formae speciales and that two separate clades were formed which may indicate specificity towards monocots or dicots, respectively (Figure 24).

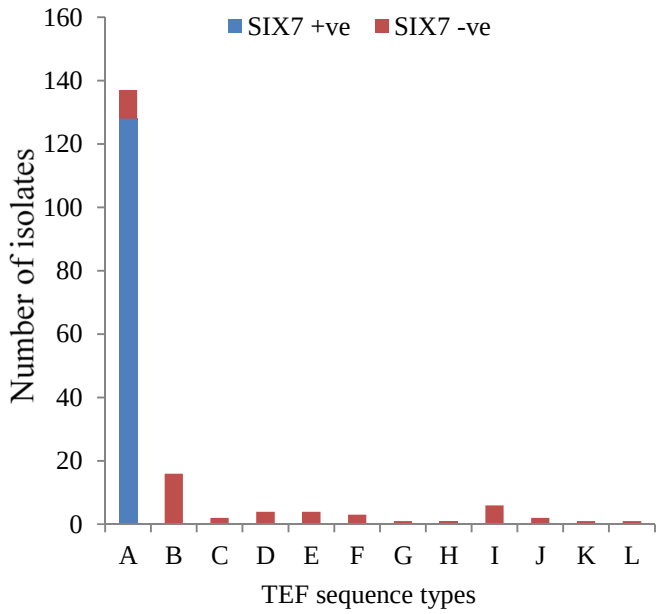

Figure 23. Frequency of *SIX7* gene among 176 *Fusarium oxysporum* isolates from *Allium* crops with reference to their TEF sequence type (FoA to FoL, see Figure 8).

In comparison with *F. oxysporum* f. sp. *lycopersici*, 91% DNA sequence identity was found for the *SIX7* homologue in *F. oxysporum* f. sp. *cepae*, 93% identity for *F. oxysporum* f. sp. *narcissi*, 95% identity for *F. oxysporum* f. sp. *pisi* race 1 and 89% identity for *F. oxysporum* f. sp. *gladioli*. A sequence alignment of representatives of ff. spp. *lycopersici, cepae, narcissi, lilii, pisi* race 1 and *gladioli*

also revealed that there are conserved and variable regions in the *SIX7* nucleotide sequence and in formae speciales *cepae, narcissi* a four bp long insertion causes a frameshift mutation whereas in the sequence of *F. oxysporum* f. sp. *gladioli* a 68 bp long deletion is present (Figure 25). *F. oxysporum* ff. spp. *lycopersici, narcissi, cepae* and *lilii SIX7* homologues were further analysed and it revealed that the proportion of replacement mutations are much higher when compared to silent mutations in the full coding sequence (675 bp) (Figure 25). For example, when FOC is compared to FOL there are two three bp long deletions (at positions 106-109 and 467-469) and a four bp long insertion (at position 494-497) which causes a frameshift mutation in the following sequence leading to stop codon at position 502-505. This could suggest that homologues *SIX7* gene of FOC encodes a shorter protein compare to FOL. The proportion of silent mutations *versus* replacement mutations before the 4 bp long insertion is 5 to 39 (S/R=5/39). This agrees with the protein sequence alignment of the four formae speciales mentioned above (Figure 26). Moreover, cloning of the *SIX7* gene into *E. coli* vectors and sequencing of clones confirmed that the insertion and all mutations are not artefacts of sequencing PCR reaction (data not shown).

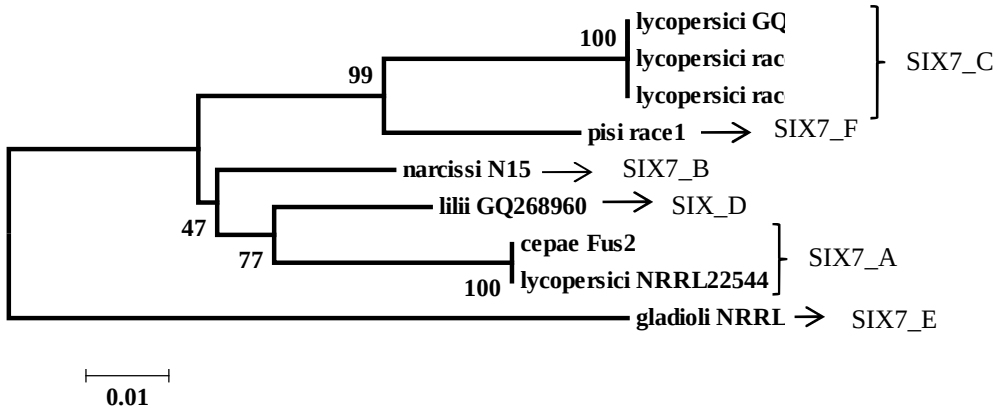

Figure 24. Cladistic tree of nine *Fusarium oxysporum* isolates belonging to six formae speciales based on "secreted in xylem 7" nucleotide sequences (*SIX7*). Consensus tree is shown with bootstrap values from 1000 replications. GenBank accession number is indicated for each reference sequence. SIX7_A- to SIX7_F refers to *SIX7* sequence types. NRRL 22544 was originally designated as *F. oxysporum* f. sp. *lycopersici*, but was found very aggressive in onion seedlings.

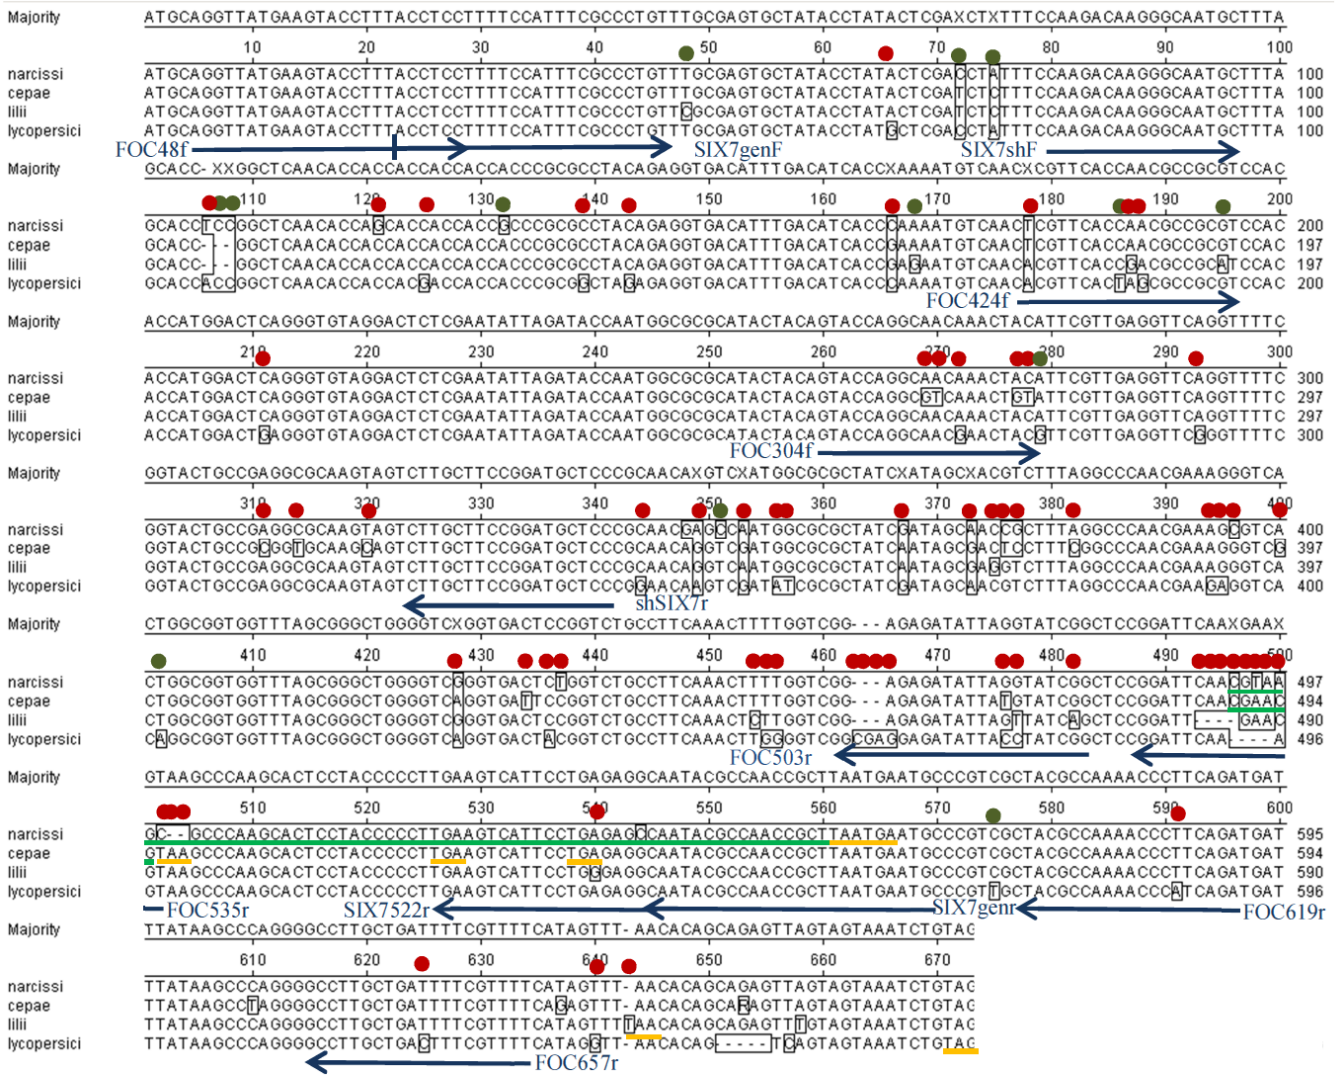

Figure 25. Multiple alignment of four nucleotide sequences: *SIX7* gene sequences of *Fusarium oxysporum* f. sp. *lycopersici* and three sequences corresponding to *SIX7* homologues of *F. oxysporum* ff. spp. *narcissi*, *cepae* and *lilii*. Differences compared to the consensus sequence are shown in boxes. Primer sequences are indicated with a blue arrow underneath the multiple alignment.
Silent mutations are indicated with a green spot above the multiple sequence alignment.
Replacement mutations* are indicated with a red dot above the multiple alignment.
Frame shift mutations* are underlined in green.
Stop codons are shown with a yellow line.

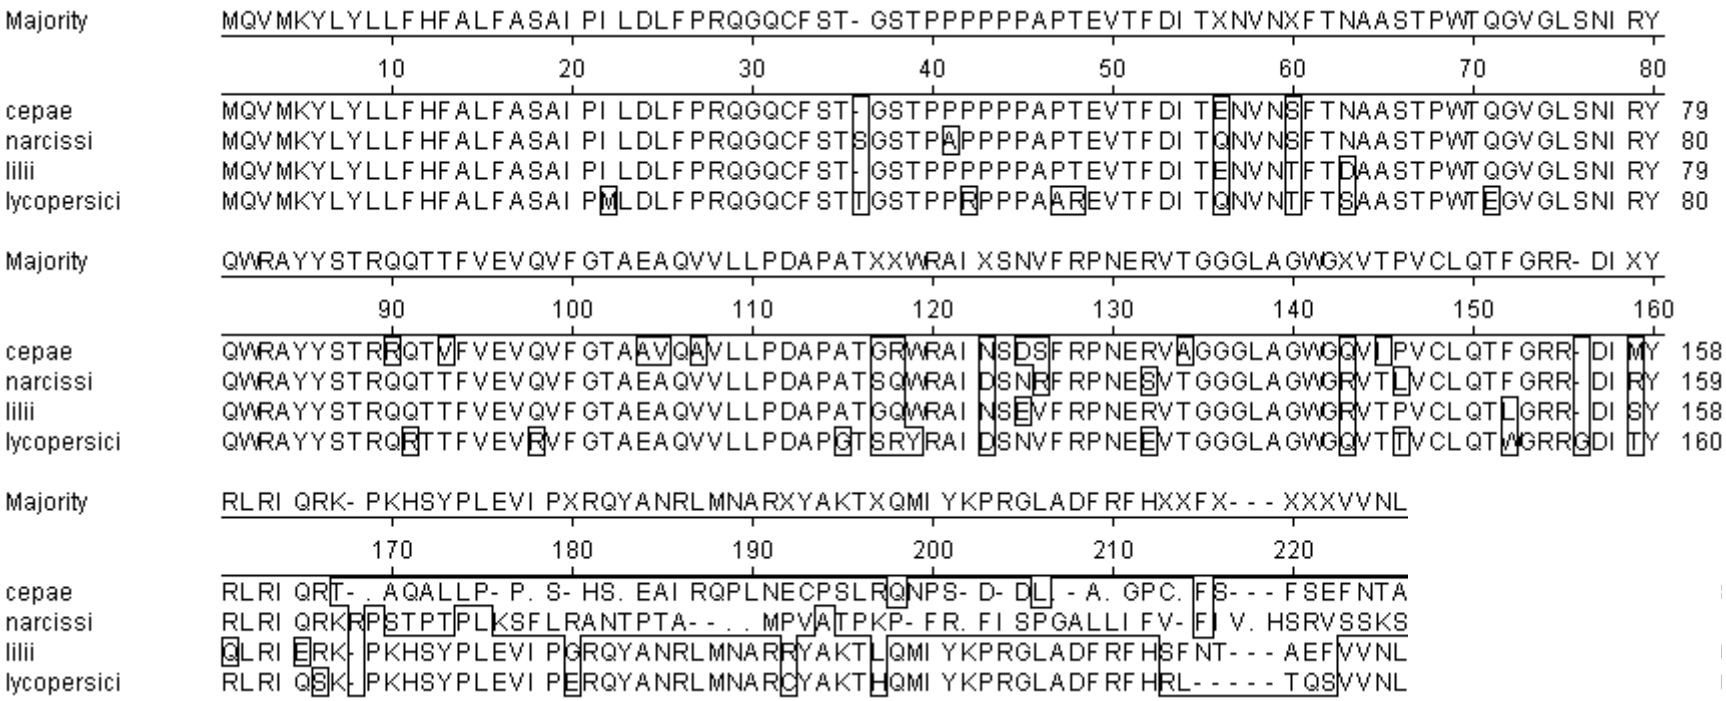

Figure 26. Multiple alignment of four protein sequences: *SIX7* gene sequence of *Fusarium oxysporum* f. sp. *lycopersici* and three sequences corresponding to *SIX7* homologues of *F. oxysporum* ff. spp. *narcissi*, *cepae* and *lilii*. Differences compare to consensus sequence are shown in boxes.

Primers (12) were designed on various regions of *SIX7* (Table 16) to confirm the presence / absence of the homologue of this gene in *F. oxysporum* ff. spp. *cepae* (Fus2, D2, GR4), *lycopersici* (FOLR1), *medicaginis* (Fom004) and *F. oxysporum* isolates tested non-aggressive in onion seedlings (A13, 151, A28; Table 17). None of the tested primer pair combinations (FOC403f/FOC535r, FOC403f/SIX7522r, FOC403f /FOC503r, FOC48f/FOC657r, FOC424f/FOC619r, SIX7genF/SIX7genR, SIX7shF/ SIX7shR; Tables 16 - 17) gave a product with D2 and Gr4 (very aggressive isolates). On the other hand, the shSIX7F/ShSIX7R primer pair (designed on the conserved region of *SIX7*) generated a band with the A13 isolate, which was found non-aggressive in onion seedlings. The A13 *SIX7* fragment was sequenced and it was identical to the ST SIX7_A. FOC-specific FOC304f and FOC353r primers gave a product only with FOC isolate Fus2 isolate, but were negative for *F. oxysporum* f. sp. *lycopersici* (FOLR1).

The combined dataset of 40 *F. oxysporum* isolates was analysed in relation to presence/sequence of *SIX7* homologue and results of onion seedling assay (Table 18, Figure 27).

All non-A type *SIX7* isolates and A13 isolate carrying a truncated or mutated version of *SIX7* were exclusively found to be non-aggressive (Figure 27). Whereas isolates harbouring the A type of *SIX7* homologue and *SIX7* negative isolates could be aggressive or non-aggressive (Table 18, Figure 27). Aggressive isolates not carrying the *SIX7* homologue were recovered from onion, leek, shallot and garlic. Non-aggressive strains carrying type A sequence of the *SIX7* homologue were isolated from onion and leek (Table 18).

SUMMARY

A homologue of a previously published effector gene of FOL, *secreted in xylem 7* (*SIX7*), has been found in some of the FOC isolates, but not all of them. It was also shown that homologues of *SIX7* were only identified for some of the isolates when amplified by primers designed on conserved regions. Extensive PCR-based screening of 176 *F. oxysporum* isolates from *Allium* crops showing basal rot symptoms for the presence of *SIX7* homologues led to the discovery of *SIX7*'s limitation to one *TEF* ST of FOC, FoA. Genome sequencing of a very aggressive FOC isolate Fus2 led to the discovery of the homologues of further published effector genes, namely *SIX3, SIX5* and *SIX9*. This is the first report of the discovery of a homologue of *Fol-AVR2* (=*Fol-SIX3*) and *Fol-SIX5* in another forma specialis than FOL. Overall, *SIX3, SIX5* and *SIX7* are useful for the robust identification of some of the very aggressive FOC isolates, although some FOC isolates lack these genes.

In order to isolate further effector genes of *Fusarium oxysporum* f. sp. *cepae*, a whole genome sequencing approach was chosen and this work is discussed in Chapter 4.

3.5 DISCUSSION

Pathogenic and saprophytic *F. oxysporum* can co-exist in the same cropping system. Identification of *F. oxysporum* isolates at a sub-species level is essential for disease management purposes (Lievens *et al*., 2007). Onion basal rot in the UK is an increasing problem and it is mainly caused by FOC (Chapter 2 and Chapter 3). Prevention is the best way to control this soil-borne pathogen, which requires FOC-free onion seeds, sets and soil for crop production. The research in this chapter was focussed on genetic diversity in a collection of *F. oxysporum* isolates from *Allium* species using onion pathogenicity assay and molecular markers, such as housekeeping genes, microsatellite markers and effector genes to develop FOC-specific markers.

3.5.1 Cladistic analysis of *F. oxysporum* isolates associated with diseased *Allium* species and different formae speciales based on *TEF* sequences

FOC isolates showing diversity based on *TEF* sequence variation were analysed by neighbour-joining and maximum likelihood methods. Isolates formed two main clades, Clade 2 and Clade 3 having been determined by O'Donnell *et al*. (1998a), as supported by the position of isolates used in original study mentioned above. This result agrees with a previous study by Galvan *et al*. (2008) where a worldwide collection of 29 FOC isolates was analysed using AFLP markers. Isolates classified as belonging to sequence types (STs) FoA, FoB and FoD cluster closely, suggesting a clonal origin of these groups, although these clonal lineages were identical to representatives of other formae speciales based on partial *TEF* sequence similarity. For example, the most commonly occurring clonal lineage FoA comprises

identical *TEF* sequences of cultures pathogenic to *Allium* species, tomato, peas, freesia alfalfa and asparagus. The diversity of isolates from *Allium* species indicates the polyphyletic origin of FOC. This finding agrees with previous research, several formae speciales such as *cepae*, *lycopersici*, *freesia*, *pisi*, *asparagi*, *medicaginis*, *gladioli* and *dianthi* were described as polyphyletic (Galvan *et al*., 2008; Baayen *et al*., 2000).

3.5.2 Onion seedling assay using *Fusarium* isolates from diseased *Allium* species and different formae speciales

Classically, the identification of host specific forms of *F. oxysporum* is done by time-consuming and laborious pathogenicity assays. Moreover, pathogenicity testing does not give information on host specificity of strains determined as non-pathogenic towards a few tested plants (Leslie and Summerell, 2006).

A previously developed seedling assay (Taylor *et al*., 2012) was used in this study to characterise *Fusarium* isolates associated with onion basal rot. This assay was chosen because it provides relatively rapid results that are consistent with disease severity observed using a more laborious onion bulb rot assay. Taylor *et al*. (2012) compared both assays using under the same glasshouse conditions. In the bulb rot assay, onion sets were grown in *Fusarium* infested soil for six months, and observed basal rot symptoms (pink mycelium development on basal plate and browning scales) in the susceptible control. The seedling assay was completed in four weeks, and gave consistent results with less expensive and labour, which is very important for large-scale characterisation of *Fusarium* isolates and onion cultivars.

There was a significant variation in aggressiveness among *F. oxysporum* isolates from different sources and locations in the UK. These results agree with previous studies from Japan (Dissanayake *et al.*, 2009ab) where 13 *F. oxysporum* isolates were tested on Welsh onion seedlings and were found to be strongly, moderately and non-aggressive.

The results also confirmed that *F. proliferatum* was pathogenic on onion, although there was variation in pathogenicity. *F. solani* and *F. redolens* were found on onions grown in the UK as frequently as *F. proliferatum*, but the results of the pathogenicity assay suggested that they are not causal agents of onion basal rot. *F. redolens* was tested as non-aggressive in an onion seedling assay in Japan (Dissanayake *et al*., 2009ab). On the contrary, *F. solani* and *F. redolens* isolates from onion were found to be pathogenic in Turkey (Bayraktar *et al*., 2010). The simplest explanation for this difference is that the *F. solani* and *F. redolens* isolated from British onion occur as secondary invaders rather than as pathogens. However, only two *F. solani* and four *F. redolens* isolates were included in our pathogenicity assay and these could be atypical. This disagreement could also be explained by the lack of negative standard (*e.g*. non-aggressive Fo47 strain) in assays employed by other research institutes, where only water was used as negative control. Results of the seedling assay using Spanish *F. proliferatum* and *F. acuminatum* isolates showed that they can cause damping-off symptoms (Palmero *et al*., 2012), which also agrees with a previous publication from Turkey (Bayraktar *et al*., 2010). Prior evidence in the literature for the presence of *F. proliferatum* and *F. acuminatum* in association with onion basal rot in Spain and Chile was not found. One of the *F. oxysporum* isolates from the Dutch set was found to be very aggressive in onion seedlings. This suggests that FOC can spread by infected planting material between countries.

3.5.3 Molecular identification of *F. oxysporum* isolates using DNA sequence variation in housekeeping genes

Four housekeeping genes *TEF*, calmodulin, B-tubulin and *RPB2* were used for the characterisation of 40 *F. oxysporum* strains representing *F. oxysporum* ff. spp. *cepae, lycopersici, pisi, medicaginis, asparagi, freesia, dianthi, gladioli* along with non-aggressive isolates recovered from onion and biocontrol strain Fo47. The combination of the four datasets led to the identification of 19 sequence types (STs). Two of these (ST4 and ST8) correlated with aggressiveness in onion seedlings. However, four sequence types (STs 1- to 3 and ST6) comprised both aggressive and non-aggressive isolates. Within these sequence groups, all isolates recovered from non-*Allium* hosts were found non-aggressive in onion seedlings, except for isolate NRRL22544 which was misidentified as belonging to *F. oxysporum* f. sp. *lycopersici*. *TEF, RPB2*, B-tubulin and calmodulin genes have not been used together to characterise pathogen populations. However, 18 formae speciales were characterised by β-tubulin, *TEF*, microsatellites and AFLP, but none of these markers were able to differentiate representatives of different host-specific forms of *F. oxysporum* (Bogale *et al*., 2006). *RPB2* was first used to characterise *Fusarium* pathogen populations in a study based on 126 clinically important fusaria (O'Donnell *et al*., 2007). However, *RPB2* has not been used before to characterise *F. oxysporum* representing various formae speciales *RPB2* and *TEF* were more informative compared to calmodulin and β-tubulin, and therefore more appropriate for phylogenetic studies, as suggested by other researchers (Poucke *et al*., 2012).

3.5.4 Molecular identification of *F. oxysporum* isolates using microsatellite markers

Microsatellite markers provide a powerful tool to study taxonomy and population genetics (Jimenez-Gasco *et al*., 2003). In this study, five previously published microsatellite markers were tested to determine the intraspecific variation within the *F. oxysporum* species complex. In total, 26 unique haplotypes were found among 40 *F. oxysporum* isolates representing various formae speciales FOL 356 and FOL 245 were found more informative than MB2 and FOL35, while FOL680 did not show a high level of variation. Loci FOL 35 and FOL 680 had the highest diversity in *F. oxysporum* ff. spp. *lycopersici* and *radicis-lycopersici* (Almany *et. al*., 2009), while loci MB2 showed the highest diversity of isolates from Ethiopian soil and plant tissue (Bogale *et al*., 2005). A Blast search of microsatellite targeting primers revealed that none of these markers are present on lineage specific regions.

Some of the microsatellite patterns could be linked to aggressiveness in onion seedlings (*e.g*. HT14, HT20, HT21 and HT22). However, three haplotypes comprised both aggressive and non-aggressive isolates: HT10, HT13 and HT18. HT13 comprised the misidentified *F. oxysporum* f. sp. *lycopersici* isolate NRRL22544. Apart from this, all other isolates were recovered from *Allium* species regardless of their aggressiveness in onion seedlings (Table 13). This means that microsatellites were not useful to distinguish aggressive and non-aggressive isolates of *Fusarium oxysporum*, which was also found by Bogale *et al*. (2006). However, if the onion isolates that tested non-aggressive in HT10, HT13 and HT18 (isolates A19, FOB and 151) are atypical due to cultural instability caused by repeated sub-culturing, in that case the combination of five microsatellites tested enables us to

identify *F. oxysporum* f. sp. *cepae* (Leslie and Summerell, 2006; de Visser and van den Broek, 2005), although this is just speculation.

3.5.5 Molecular identification of *F. oxysporum* isolates using microsatellite markers designed on mobile pathogenicity chromosome of FOL

Lineage specific regions and chromosomes in the genome of *F. oxysporum* f. sp. *lycopersici* 4287 were directly linked to pathogenicity towards tomato (Ma *et al*., 2010). The objective of this small study was to develop microsatellite markers on these lineage specific regions for the characterisation of the *F. oxysporum* species complex.

Several microsatellite markers were developed on supercontig 36 of *F. oxysporum* f. sp. *lycopersici* strain 4287 (FOL4287) harbouring some of the virulence genes. Unfortunately none of these markers gave products with all FOC isolates. This could mean that the different clonal lineages of FOC share different pathogenicity chromosomes. Those isolates that gave PCR products with primers designed on lineage specific region of FOL4287 carried similar lineage specific regions to the tomato pathogens. The comparative study of 11 plant pathogenic *F. oxysporum* strains representing eight formae speciales showed that genome-wide rearrangements can happen in a short evolutionary divergent time and this genomic plasticity that enables organism to adapt to their hosts (presentation by Dr Li Jun Ma at the ECFG11 conference, Marburg, Germany 2012).

3.5.6 Molecular identification of *F. oxysporum* isolates using effector genes

Identification of *F. oxysporum* ff. spp. *lycopersic*i (FOL) and *vasinfectum* based on effector genes was found to be a very robust identification method (Lievens *et al*., 2009a; Chakrabarti *et al*., 2011). It was also discovered that some of these effector genes are not restricted to only one formae speciales (Lievens *et al*., 2009a). Therefore, the aim of this study was to screen FOC isolates for the presence of previously published effectors and use it to develop specific primers.

Screening of seven effector genes led to the discovery of homologues of *SIX7* gene in Fus2 isolate belonging to FOC. A homologue of *SIX7* was previously found in *F. oxysporum* f. sp. *lilii* (Lievens *et al*., 2009a). Homologues of *SIX6, SIX8, OXRED* and *FTF1*genes were absent in isolate Fus2 using the primer pairs employed in the current study. It is likely that homologues of these genes are actually present but due to mutations in the primer annealing site, they were not detected. It was also shown that homologues of *SIX7* were only identified for some of the isolates when amplified by primers designed on conserved regions.

Extensive screening of 176 *F. oxysporum* isolates from *Allium* crops for the presence of *SIX7* homologues led to the discovery of *SIX7*'s limitation to one clonal lineage of FOC. The homologue of *SIX7* was only present in the most representative *TEF* sequence type FoA, but not in the other *TEF* STs. Screening of twelve other formae speciales led to the discovery of homologues of *SIX7* in *F. oxysporum* ff. spp. *narcissi*, *gladioli* and *pisi* race 1. Surprisingly, no *SIX7* genes were found in *F. oxysporum* f. sp. *gladioli* by Lievens *et al*. (2009). Comparison of the sequences of *SIX7* homologues revealed that they evolve faster compared to housekeeping genes, possibly due to positive selection. The *SIX7* gene of FOC is strongly conserved

among the representatives of this f. sp., which agrees with previous research (Lievens *et al*., 2009a; Thatcher *et al*., 2012).

Remarkably, the *SIX7* sequence of the NRRL22544 isolate was identical to the sequence of FOC isolates which agrees with the results of the onion seedling assay, therefore it is likely that this isolate was misidentified as belonging to FOL. To confirm this, host specificity of NRRL22544 needs to be tested on tomato as well as onion. This finding shows there is a need for reliable identification methods to distinguish formae speciales.

Primer pairs designed on the conserved regions of *SIX7* revealed the presence of a mutated or truncated version of this gene in a non-aggressive isolate from onion (A13). This finding is supported by the results of sequence comparison of *SIX7* homologues. The *SIX7* protein is likely to be shorter due to frameshift mutation when compared to the one in FOL. Moreover, primer pairs designed on the conserved region of the *SIX7* gene can be used for the reliable screening for the presence of this gene. On the other hand, primers designed on the variable regions of *SIX7* can be used to predict host specificity of several formae speciales. Unfortunately, *SIX7* is not present in all FOC isolates therefore it is not applicable to identify all onion-specific *F. oxysporum* isolates. However, the homologue of *SIX7* is present in the majority of FOC isolates in our collection, which suggest that it could be still valuable for identification methods using multiple loci. Surprisingly, two isolates (A19 and FOB) tested as non-pathogenic harboured *Foc-SIX7* gene, which suggests that these isolates may have lost their pathogenic ability due to cultural instability or epigenetic differences (Leslie and Summerell, 2006; Michielse *et al*., 2009, de Visser and den Broek, 2005).

One explanation for the lack of *SIX7* in some FOC isolates could be that the loss of *SIX7* is advantageous to overcome plant immunity (Takken and Rep, 2010). If the Six7 protein is recognised by *Allium* plants, FOC might have tried to escape recognition by losing *SIX7*. For example, FOL race 1 isolates differ from FOL race 2 and FOL race 3 isolates in the presence of an effector gene, *SIX4* (=*AVR1*), which was lost from FOL race 2 and FOL race 3 to avoid recognition by tomato plant immunity (Houterman *et al*., 2008; Takken and Rep, 2010). The other strategy to overcome plant immunity is by mutating effectors in order to avoid recognition as it happened in FOL; *Fol-SIX3* of FOL race 2 differs in two amino acids from FOL race 3 isolates. It has to be noted that no races have been discovered within FOC yet; therefore it is only a hypothesis. Moreover, it is also possible that the *SIX7* homologue of FOC is not functioning, due to the missense mutation, therefore it could become dispensable. Another hypothesis is that *SIX7* is not crucial for pathogenicity and it is located in a region of a chromosome be easily lost, or else *SIX7* was gained by these strains. This suggests that there is another set of effector gene(s) which are involved in host specificity and pathogenicity in FOC. This predicted gene(s) could be used for robust identification of *F. oxysporum* pathogenicity towards onion.

CHAPTER 4

GENOME SEQUENCING OF A *FUSARIUM OXYSPORUM* F. SP. *CEPAE* ISOLATE AND IDENTIFICATION OF CANDIDATE EFFECTOR GENES

4.1 INTRODUCTRION

This chapter focuses on the possible ways of identifying candidate effector genes applicable for the development of a *F. oxysporum* f. sp. *cepae* (FOC)-specific molecular methodology. A whole genome sequencing approach was chosen to identify candidate effector genes in the genome of a FOC isolate. This only provides preliminary results and future prospective are discussed.

4.1.1 Definition of effectors

Effectors can be defined as small secreted proteins that alter host cell structure and function, facilitate infection and suppress or activate effector-triggered immunity (van de Wouw and Howlett, 2011). Kamoun (2009) defined effectors as "molecules that alter host cell structure and function, thereby facilitating infection (*i. e.* virulence factors or toxins) and/or triggering defence responses (*i.e.* avirulence factors or elicitors)". Effectors can also be defined as "secreted proteins and other molecules which allow plant-associated organisms to modulate plant defence circuitry and enable colonization of plant tissue" (Hogenhout *et al*, 2009). Brown and his colleagues (2012) expanded that 'effectors' that modulate the interaction between pathogenic microbes and hosts have been identified from all (mutualistic, biotrophic, hemibiotrophic, necrotrophic and saprophytic) lifestyles".

In this chapter the definition of effectors is used as by Hogenhout *et al*. (2009). Characteristics listed in the first chapter (see Section 1.9) could be useful to discover / identify novel effector genes applicable for the development of specific molecular methods.

4.1.2 Characteristics of known *F. oxysporum* effectors

This section is predominantly focusses on effectors occur in *F. oxysporum*. However, characteristics of other fungal and oomycete effectors, listed in Chapter 1, need to be considered for the identification of novel candidate effectors.

Effector proteins can be classified based on whether they interact with their target in the host apoplast or cytosol (Kamoun, 2008). *SIX* genes of *F. oxysporum* are secreted during infection into the host apoplast, and are generally small (<300 amino acids), cysteine rich (two or more) proteins with a type II secretion signal at the N-terminal (Rep, 2005; van der Does and Rep, 2007). *SIX* genes have no database representatives outside of the genus *Fusarium* (Houterman *et al*., 2007), and the only sequence similarity between them was found in their promoter region, where a transposable element, mimp1, is harboured in all *SIX* genes (Sarah Schmidt, University of Amsterdam, pers. comm.).

Almost all known *SIX* genes of *F. oxysporum* f. sp. *lycopersici* (FOL) are coded on a mobile, lineage specific chromosome (chromosome 14) which is rich in transposable elements (Ma *et al*., 2010). Similarly, the first conditionally dispensable chromosomes encoding genes that are required for pathogenicity on pea, such as *pea pathogenicity* (*PEP1*, *PEP2*, and *PEP5* genes) and the *pisatin demethylase* (*PDA1*) gene, were discovered in the genome of *Fusarium solani* f. sp. *pisi* (Han *et al*. 2001).

The FOL effector gene *SIX1* (termed *Fol-SIX1*) is highly up-regulated during colonisation and requires living plant cells as only 5–20% of hyphae express *Fol-SIX1* when growing in tomato cell cultures (van der Does *et al*., 2008). Expression of the *Fo5176-SIX4* homologue of the *Arabidopsis* pathogen *F. oxysporum* was 18- to 70- fold less when grown on PDA plates compare to that measured *in planta* (Thatcher *et al*., 2012). In some fungi, effectors are highly expressed during nitrogen

starvation (Snoeijers *et al*., 1999, Stephenson *et al.,* 2000; Talbot *et al*., 1993) although in *F. oxysporum,* no up-regulation of effector genes was detected during nitrogen starvation of FOL (Divon *et al*., 2005), but a very low secretion was observed when the fungus was grown on minimal medium with sucrose and KNO_3 (van der Does and Rep, 2007).

Recently, two possible effector encoding genes, *putative effector protein 1* (*Fov-PEP1*) and *Fov-PEP2*, have been discovered from *F. oxysporum* f. sp. *vasinfectum* (FOV) (Chakrabarti *et al*., 2011). These genes were identified in a cDNA library of 2100 clones isolated from cotton seedlings infected with FOV under tissue-culture conditions (McFadden *et al*., 2006) and selected on the basis of criteria such as short, cysteine rich, secreted, had no database representatives at all or outside of *Fusarium* genus and was only present in FOV isolates. A homologue of *Fov-PEP1* is present in the FOL genome sequence as a single copy gene on chromosome 14, interrupted by a retrotransposon, while *Fov-PEP2* had no homologues in the FOL genome at all.

4.2 AIMS AND OBJECTIVES

The aims of this part of the project were:

- To obtain the whole genome sequence of a *F. oxysporum* f. sp. *cepae* (FOC) to identify candidate effector genes in a representative isolate
- To screen a set of candidate effector genes in a collection of *F. oxysporum* isolates representing several formae speciales for the presence / absence.
- To compare the sequences of putative effector genes from different formae speciales
- Evaluate and test bioinformatics tools and markers for the identification of further effector genes

4.3 MATERIALS AND METHODS

4.3.1 Preparation of DNA samples for genome sequencing of *F. oxysporum* f. sp. *cepae* (FOC)

4.3.1.1 Description of FOC isolate chosen for genome sequencing

A very aggressive FOC strain, Fus2, was used for whole genome sequencing. Fus2 was isolated from onion grown in Lincolnshire, UK and has been used to screen onion cultivars for resistance and also to test effectiveness of biocontrol treatments (Taylor *et al*., 2012; Ralph Noble, East Malling Research, pers. comm.).

4.3.1.2 DNA extraction

The CTAB extraction method (Li *et al*, 1994 modified by Dez Barbara, University of Warwick) was employed to obtain good quality (unsheared) DNA for genome sequencing. 250 mg of freeze dried mycelium of Fus2 was homogenised with 1 g of sterile sand using a chilled, sterile pestle and mortar. The ground mycelium/sand was transferred into a 50 ml Falcon tube and mixed by inversion with 15 ml extraction buffer (8.18g NaCl dissolved in 70 ml dH_2O with 5 ml 2M pH 8.0 Tris-Cl, 4 ml 0.5M pH 8.0 EDTA, 7.4 ml 10% cetyltrimethylammonium bromide (CTAB), 13.6 ml dH2O, 2 g polyvinylpyrrolidone 40 (PVP-40) and 0.5 ml 2-mercaptoethanol). The sample was incubated at 60°C for 30 minutes and mixed gently by inverting occasionally. 15 ml of the chloroform/penta-1-ol wash (96 ml chloroform and 4 ml penta-1-ol) was added to the sample which was mixed by gentle inversion for 10 minutes followed by centrifugation. All centrifugation steps were carried out at 1500 g (2914 rpm) for 10 minutes at 20°C, unless stated otherwise. The

aqueous phase was transferred into a sterile 50 ml Falcon tube and 15 ml of chloroform/penta-1-ol wash was added again followed by gentle mixing by inversion for 10 minutes then centrifuged. The aqueous phase was transferred into a sterile 50 ml Falcon tube and centrifuged again. 0.6 volumes of cold (-20°C) isopropanol was added to aqueous phase and mixed by inverting tube gently. The sample was incubated at room temperature for 2 hours before centrifuging at 460g (1500 rpm) for 2 minutes at 20°C. The supernatant was then removed and the pellet dissolved in 10 ml wash buffer (66 ml 100% ethanol and 34 ml 0.1M NaCl) by gentle inversion for 20 minutes followed by centrifugation. Supernatant was removed and rinsed again in 10 ml wash buffer then was centrifuged. The supernatant was removed and the pellet was air dried for 20 minutes. The pellet was then dissolved in 1.5 ml Tris-EDTA (10mM pH 8.0 Tris-Cl and 1 mM EDTA) and transferred into a 1.5 ml Eppendorf tube using a pipette tip with the end cut off. The sample was centrifuged at maximum speed for 5 minutes and the supernatant was transferred into a 1.5 ml Eppendorf tube using a pipette tip with the end cut off. The sample was quantified using a Nanodrop 1000 spectrophotometer (Thermo Scientific).

4.3.1.3 RNase treatment and purification of the nucleic acid extract

RNase treatment was applied to degrade any RNA in the sample. Approximately 10µg of DNA was taken and 1 µl of RNase (Qiagen RNase A 7 U/µl) added in a total volume of 25 µl. The sample was incubated at room temperature for 30 minutes then desalted using a Qiaex II gel extraction/desalting kit (Qiagen) following the manufacturer's guidelines with a minor modification. The sample was eluted once in 30 µl of buffer EB from a QIAQuickPCR purification kit (Qiagen). The sample was quantified using a Nanodrop 1000 spectrophotometer (Thermo

Scientific) then by Qubit fluorospectrometer using a broad range dsDNA kit (Invitrogen). The DNA was diluted using buffer EB (Qiagen) to give a final volume of 75 µl and a concentration of 20 ng/µl.

4.3.1.4 Verification of purity and quality of the DNA sample

Amplification of the ITS region (using ITS1 and ITS4 primer pair and conditions published by White *et al*., 1990) and the *TEF* gene (Chapter 2) were used to ensure that the DNA sample is not contaminated and applicable for amplification.

4.3.2 Preparation of genomic DNA libraries and genome sequencing

Clone libraries containing 300-400 bp fragments were prepared by Jeanette Selby (Genomics Facility of University of Warwick) following Illumina's TruSeq DNA Sample Preparation low throughput (LT) protocol. Samples were run on an Illumina GAIIx sequencing platform which resulted in 70 bp long paired-end reads in fastq file format.

4.3.3 *In silico* analysis pipeline to identify putative effectors genes of Fus2

An *in silico* analysis pipeline was designed to identify putative effectors from the genome of Fus2 (Figure 28). Two approaches were chosen to assemble the 70 base pair long paired-end reads: template based assembly followed by *de novo* assembly of unused reads and *de novo* assembly. The first method was template based assembly using the *F. oxysporum* f. sp. *lycopersici* 4287 (FOL4287) genome and mitochondrial sequence (Broad Institute) as a reference followed by *de novo*

assembly of non-matching reads (see 4.3.3.1). The second method was *de novo* assembly utilizing all reads. Obtained contigs were screened for the presence of published effector genes (see 4.3.3.1). To identify candidate effector genes two approaches were taken. Firstly, contigs obtained through template based assembly followed by *de novo* assembly were appointed to gene prediction. Secondly, contigs obtained by *de novo* assembly and harbouring published effectors were chosen for further analysis. Characteristics of predicted genes were analysed by using various software packages and web servers (see below).

4.3.3.1 Assembly of paired-end reads

Velvet (Zerbino & Birney, 2008) was used for the *de novo* assembly of all reads. This method allows the formation of contigs based purely on their similarity to each other. This work was carried out by Dr Richard Harrison (East Malling Research).

Assembly of 70 base pair long paired-end reads by SeqMan NGen (DNAStar) using FOL4287 and mitochondrial genome (Broad Institute) as a template was employed for the identification of genomic regions highly similar to the template. Reads showing no similarities FOL4287 were not used for the template based assembly / alignment (e.g. unused reads). These unused reads were presumed to contain reads specific to the FOC genome. Unused reads were appointed to a *de novo* assembly using Geneious Pro (Drummond *et al.*, 2011; Biomatters Limited). This work was done by Riccardo Baroncelli (University of Warwick).

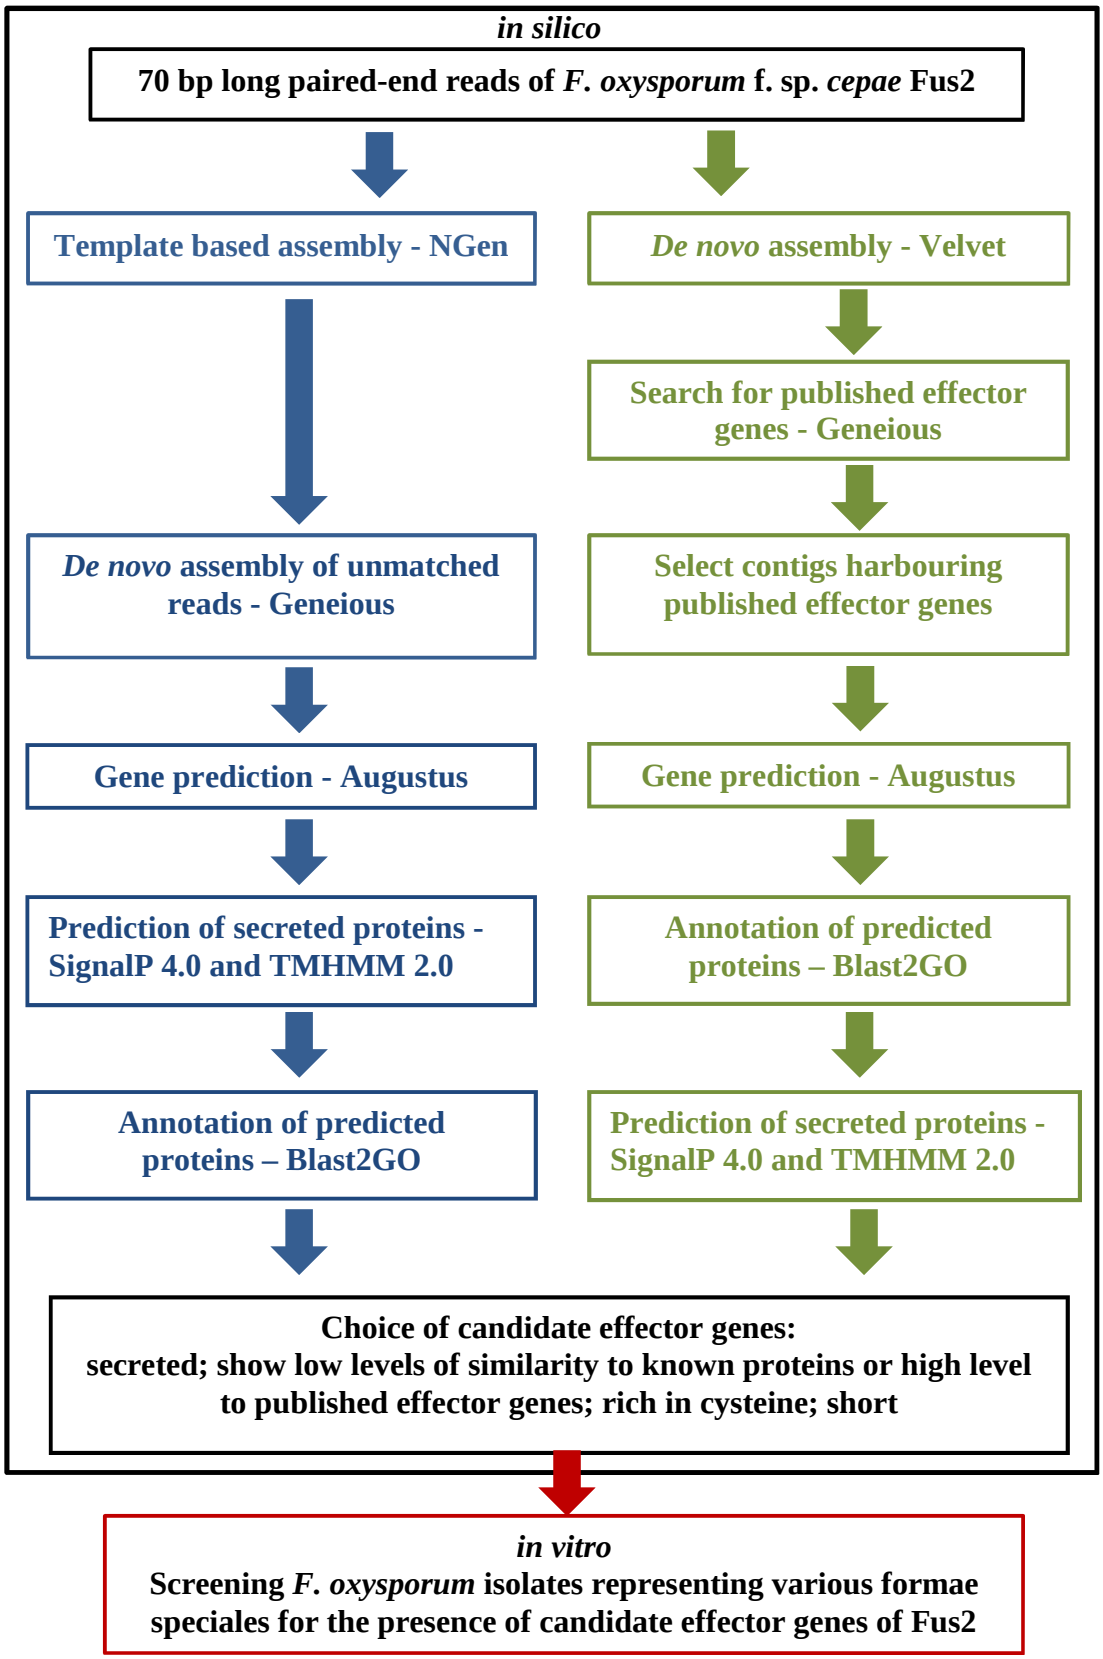

Figure 3. *In silico* analysis pipeline designed to identify putative effectors from the genome of *Fusarium oxysporum* f. sp. *cepae* (FOC) Fus2 followed by *in vitro* screening for the presence of these genes in representatives of various formae speciales.

4.3.3.2 Screening the Fus2 genome for the presence of published effector genes

The Fus2 genome was screened for the presence of effector genes (*SIX 1* to *SIX9* sequences were published by Lievens *et al*., 2009a and Thatcher *et al*., 2012) by using Custom Blast (Altschul *et al*., 1990), implemented in Geneious Pro (Drummond *et al*., 2011; Biomatters Limited).

4.3.3.3 Gene prediction on contigs

The web server Augustus (Augustus; Stanke and Morgenstrern, 2005) was employed to identify genes using default settings (predicting a few alternative transcripts on both strands) and *F. graminearum* as template.

4.3.3.4 Annotation of predicted genes

Predicted genes were functionally annotated by automated Blast-P and tBlastn-based annotation using Blast2GO (Conesa *et al*., 2005; Blast2GO). Signal peptides were predicted by SIGNALP 4.0 (Petersen *et al*., 2011; SignalP) by using the default settings. TMHMM v. 2.0 was used to filter out proteins containing transmembrane helices among secreted proteins (Krogh *et al*., 2001; TMHMM). The number of cysteines was counted by using a Python script (Holmes, 2012).

4.3.4 Choice of candidate effector genes for initial screening

Every secreted protein showing low similarity to previously published sequences was treated as a candidate effector protein. Due to the shortage of time, only eleven candidate effector genes were chosen for initial screening. Some other

criteria were also considered, for example: presence of N-terminal secretion peptide, similarity to other proteins (the lower similarity the better), presence of certain domains such as chitin or protein-binding domain, amino acid length (the shorter the better) and the number of cysteines (the more the better).

4.3.5 Screening of *F. oxysporum* isolates from diseased *Allium* crops and different formae speciales for the presence of known and candidate effector genes

Primer pairs were designed manually on the nucleotide sequences of ten candidate effector genes, *SIX3* and *SIX5* and tested on 25 of *F. oxysporum* isolates from diseased *Allium* crops and seven other formae speciales (Table 19; for primer sequences see Results). These isolates were chosen based on their aggressiveness in onion seedlings and represent the very aggressive (termed as FOC) and non-aggressive isolates with a few isolates from the middle of the scale (A13, 18B, 151, A28, Fus1 and 22).

Table 19. *Fusarium oxysporum* (25) isolates from diseased *Allium* crops and seven formae speciales used to screen for the presence of eleven candidate effector genes, *SIX3* and *SIX5*.

-: host specificity has not been defined

Composition of a 20 µl PCR mixture was: 1 µl DNA; 1 µl primer forward (20 µM), 1 µl primer reverse (20 µM), 10 µl RedTaq ready mix (Sigma-Aldrich) and 7 µl DNase free water (Sigma-Aldrich). Purification and sequencing of amplicons was carried out as described in Section 3.3.2.3. The PCR conditions were as follows: initial denaturation for 1.5 min at 94°C, followed by 35 cycles of 30 seconds denaturation at 94°C, annealing for 1.5 minute at the 57°C and extension for 2 minutes at 68°C. The program ended with a 10 minutes final extension at 72°C.

4.3.6 Screening of the Comparative *Fusarium* Database for the presence of predicted effector genes of Fus2

Genome sequences of ten additional *F. oxysporum* isolates representing several formae speciales became available in November 2011 from The Broad Institute, which allowed the screening of these isolates for the presence of candidate

effector genes selected primarily in this work. Predicted effector genes were manually annotated by BlastP and Blastn searches of the Comparative *Fusarium* Database (Broad Institute).

4.3.7 Evaluation and test bioinformatics tools and markers for the identification of further effector genes

A list of pathogenicity genes along with their amino acid sequences can be found on PHI-base (Baldwin *et al*., 2006; PHI-BASE). Fifteen genes have been published on PHI-base, which have been experimentally proven to be involved in pathogenicity of *F. oxysporum*. These genes were searched for by using Custom Blast in Geneious Pro (Drummond *et al*., 2011; Biomatters Limited). Novel motifs of secreted proteins were predicted by MEME v. 4.8.1 (Bailey *et al*., 2009; MEME). The NetNES 1.1 server was used to predict leucine-rich nuclear export signals (NES) in predicted secreted proteins (la Cour *et al*., 2004; NetNES). The Fus2 genome was screened for the presence of mimp1 elements by using custom blast in Genious Pro (Drummond *et al.,* 2011; Biomatters Limited). Fus2 contigs encoding *SIX* gene homologues were aligned to identify common motifs. Protein sequences of 49 secreted proteins of Fus2 were searched for the presence of published motifs such as RXLR-dEER (Whisson *et al*., 2007), LFLAK-DWL, (Birch *et al*., 2008), HaRxLs (Baxter *et al*., 2010), Y/F/WxC (Godfrey *et al.,* 2010), [L/I]xAR and [R/K]CxxCx12H (Yoshida *et al*., 2009), YxSL[R/K] (Levesque *et al*., 2010), G[I/F/Y][A/L/S/T]R (Catanzariti *et al*., 2006) and [R/K/H]x[L/M/V/F/Y/W]x (Kale, 2012) using a Python script (Holmes, 2012).

4.4 RESULTS

4.4.1 Preparation of DNA sample and genomic library for genome sequencing of FOC

A DNA concentration of 1730 ng/µl was obtained using the CTAB method, based on NanoDrop measurement. This sample was treated by RNase and purified by QIAEX kit (Qiagen) two consecutive times (sample A and B), which resulted in concentrations of 18.1 ng/ µl and 27.6 ng/ µl based on Qubit measurements (Table 20). There was a considerable difference in the concentrations measured by Nanodrop and Qubit. Surprisingly the purity of DNA extracts (A and B) were much lower compared to the original CTAB extracts (Table 20). *TEF* and ITS sequences did not indicate contamination or inhibition of the DNA sample (data not shown).

An assembly of 27,514,370 paired-end reads were generated which resulted 1,926,005,935 bp in total and provides about 40x coverage of the FOC genome.

Table 20. Quality and quantity of DNA sample used for genome sequencing of *Fusarium oxysporum* f. sp. *cepae* isolate Fus2.

Sample	Treatment	Concentration (ng/µl) by NanoDrop	Concentration (ng/µl) by Qubit	260/280 ratio*	260/230 ratio*
Fus2	CTAB extraction	1730	n.i.	2.04	2.10
Fus2 (A)	RNase treatment and desalting	89.7	18.1	1.31	0.31
Fus2 (B)	RNase treatment and desalting	94.4	27.6	1.30	0.33

Fus2 (A) and (B): A and B refers to that Fus2 CTAB extract was RNase treated and purified two (A & B) times; n.i.: no information
260/280 ratio: The ratio of absorbance at 260 nm and 280 nm is used to assess the purity of DNA and RNA. A ratio of ~1.8 is generally accepted as pure for DNA.
260/230 ratio: The ratio of absorbance at 260 nm and 230 nm is a secondary assessment of the purity of DNA and RNA. Expected 260/230 values are in the range of 2.0-2.2.

4.4.2 *In silico* analysis pipeline based on *de novo* assembly to identify candidate effectors from the genome of Fus2

The assembly of 26,293,973 out of 27,514,370 70 base pair long paired-end reads by Velvet (Zerbino & Birney, 2008) resulted in 1511 contigs (maximum 1,268,561 bp long) and an N50 of 184 kb. The estimated size of Fus2 genome was 49.99 Mb. *In silico* screening of obtained contigs for the presence of nine published effector genes (*SIX1 – SIX9*) led to the discovery of the homologues of *SIX3*, *SIX5*, *SIX7* and *SIX9* in the genome of Fus2 (Table 21).

Table 21. Location and similarity of four published effectors of *Fusarium oxysporum* f. sp. *lycopersici* 4287 (FOL) genes in the genomes of FOL and *F. oxysporum* f. sp. *cepae* Fus2 (FOC).

Gene	Description	FOL	Similarity*	FOC
SIX7	Secreted in xylem 7	Chr 14, Sup 51,	87%	NODE_1912
SIX9	Secreted in xylem 9	Chr 14, Sup 22	82%	NODE_6613
SIX3	Secreted in xylem 3	Chr 14, Sup 36, 5017-5484+	86%	NODE_11583

*using tBLastx algorithm,
FOL: Chromosome of FOL4287; FOC: Contig of Fus2
Chr: chromosome, Sup: supercontig

Amino acid similarities between Foc-Six3, Foc-Six5, Foc-Six7 and Foc-Six9 and their homologs of FOL were 86, 73, 87 and 82%, respectively (Table 22). *Foc-SIX5* and *Foc-SIX7* were found on relatively short contigs: 1470 bp (NODE_1095) and 2798 bp long contigs (NODE_1912), respectively. *Foc-SIX9* and *Foc-SIX3* were encoded on slightly longer contigs: 6117 bp (NODE_6613) and 27198 bp (NODE_11583) (Table 22). *Foc-SIX3*, *Foc-SIX5*, *Foc-SIX7* and *Foc-SIX9* shared 90%, 87%, 90% and 88% nucleotide similarity with their homologues of FOL, respectively (Figure 29, Appendix VI). Forty-five mutations were present in *Foc-SIX3* when compared to *Fol-SIX3* and 23 of these mutations resulted in amino acid

change (Figure 29). Furthermore, it has to be noted that none of these homologues of FOC were found on the same contig, while only 1222 bp separates *Fol-SIX3* and *Fol-SIX5* in the genome of FOL (Table 21). Also, no homologues of *SIX3* (=*AVR2*) and *SIX5* of FOL, have been reported to be present from any other formae speciales previously; therefore they were subjected to further analysis.

Figure 29. Multiple sequence alignment of *SIX3* nucleotide (top) and amino acid (bottom) sequences of *Fusarium oxysporum* f. sp. *cepae* (FOC) and *F. oxysporum* f. sp. *lycopersici* (FOL) race 2 and race 3.

A 27,198 bp long contig (NODE_11583) was subjected to gene prediction that resulted in nine predicted proteins (g1-g9) (Figure 30). The length of the

predicted proteins varied between 155 and 1154 amino acids (Table 22). Two out of nine predicted proteins (g3 and g5) did not show any similarities to known proteins deposited at NCBI database (NCBI) although based on coding sequence it showed 97% similarity to a hypothetical protein of the *Arabidopsis* pathogenic *F. oxysporum* isolate Fo5176. G8 was annotated as a homologue of *SIX3* by Blast2GO (Conesa *et al*., 2005). Annotation of the six remaining predicted proteins revealed the presence of homologues of two transposable elements (g6 and g7), a transcription factor (g4, btb poz domain-containing protein), a NADH oxidase (g1) and two hypothetical proteins (g2 and g9).

As *g5* did not show any similarity to any previously deposited sequences it was chosen for further analysis along with *SIX3* and *SIX5* effector genes. Overall, 25 *F. oxysporum* isolates representing seven formae speciales were screened, using newly developed primers (Table 23), for the presence of *SIX3, SIX5* and *g5* (Table 24). This experiment revealed that *SIX3* was only present in FOL as expected, a few isolates from onion and leek, and surprisingly, one isolate (NRRL 26222) representing *F. oxysporum* f. sp. *dianthi*. Interestingly, a homologue of *SIX3* was not detected in any isolates very aggressive toward onion seedlings.

A-E: PCR product present, -: gene absent
[a]Survival index: Percentage survival of onion seedlings (angular transformed data), see Chapter 3
[b] For detailed description of *SIX7* screening see Chapter 3.

SIX3 sequences of all five isolates from onion and one from leek were identical (A), while isolates from tomato and carnation (*Dianthus* sp.) were representing two different sequence types (B and C) (Table 24). Overall, all isolates found positive for the presence of *SIX3* were also positive for *SIX7* (*SIX7* screening can be found in Chapter 3).

G5 was present (Table 24) in onion isolates that harboured *SIX3* and additionally in an isolate from leek (18B) and in *F. oxysporum* f. sp. *medicaginis* (isolate Fom004), although based on the sequences of both they were different (B and C) from onion isolates (A).

SIX5 was found in more isolates from *Allium* hosts compared to *SIX3*-positives: PR7, PR5, 151 and A28 were found to contain *SIX5* but not *SIX3* (Table 24). The only exception to this is one onion isolate, A13, which was *SIX3*-positive and *SIX5*-negative. Some of the non-aggressive isolates possessed identical *SIX5* sequence to very aggressive isolates. Overall, more sequence types (A - E) were distinguished within *SIX5* than *SIX3* and *SIX7*.

SUMMARY

Genome sequence analysis revealed that there are at least four homologues of published *SIX* genes (*SIX7, SIX3, SIX5* and *SIX9*) present in the genome of FOC Fus2. Additionally, a candidate effector gene (*g5*) was identified on the contig encoding *SIX3* of FOC. Novel primer pairs were developed to amplify three (candidate) effector genes of FOC, namely *SIX3, SIX5* and *g5*. Primers were screened on a set of 25 *F. oxysporum* isolates from diseased *Allium* species and different formae speciales. Interestingly, all isolates found positive for the presence of *SIX3* were also positive for *SIX7* (*SIX7* screening can be found in Chapter 3). The presence

/ absence of candidate effector genes of Fus2 suggests that the more of these genes that are present in a *F. oxysporum* strain the more likely it is to be more aggressive in onion seedlings. However, four of the very aggressive isolates (based on onion seedling assay), namely D2, 180, SM54 and SP7-2 were found negative for all three markers screened (*SIX3*, *SIX5* and *g5*).

4.4.3 *In silico* analysis pipeline based on template based assembly to identify candidate effector genes

The combination of template (FOL4287) based and *de novo* assembly of paired-end reads of Fus2 identified 85 unique contigs (10,162-87,720 bp long) which were not present in the genome of FOL4287 and presumably contain FOC-specific regions. In total, 509 proteins were predicted over these 85 contigs of Fus2 (Appendix VII).

In total 42 out of 509 proteins were predicted to encode N-terminal signal peptides. One protein (g66) out of 42 was predicted to be a transmembrane protein, therefore not listed in Table 25. Annotation of these 41 secreted proteins indicates that plant material degradation (29%), proteolysis (10%), chitin synthesis and metabolism (20%), cell defence (2%), protein-protein interaction (5%), hydrolysis (5%), pathogenicity (7%) seem to be important for host adaptation (Table 25, Figure 31). Unfortunately, 22% of predicted secreted proteins could not be annotated.

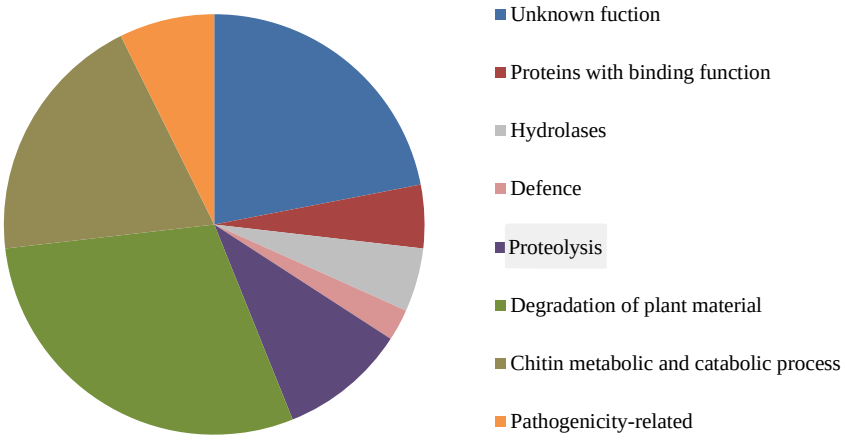

Figure 31. Functional annotation of secreted proteins of *Fusarium oxysporum* f. sp. *cepae* Fus2 not present in *F. oxysporum* f. sp. *lycopersici* 4287 genome.

Table 25. Nucleotide length, similarity to closest hit in NCBI database based on amino acid and nucleotide sequence and functional annotation of 41 secreted proteins coded on genomic regions of *Fusarium oxysporum* f. sp. *cepae* isolate Fus2 differing from the genome of *F. oxysporum* f. sp. *lycopersici* 4287 (Broad Institute). Proteins chosen for screening among *F. oxysporum* isolates from diseased *Allium* crops and different formae speciales are shown in **bold.**

Name of secreted protein contains information on the contig where it was predicted on, the individual name of the protein on given contig (number written after letter g)
Background colouring corresponding to Figure 31
No of C: number of cysteines in predicted protein

Several fungal chitinases were found among 41 secreted proteins of Fus2 (Table 25), such as V chitinase (bacterial/fungal) (g192) and class III (fungal/plant) chitinase 1 and 2 (g93 and g147). Fungal/bacterial chitinases are secreted enzymes that have been shown to play a role in the digestion and utilisation of fungal chitin, while fungal/plant chitinases have been shown to play a role during fungal morphogenesis (Hartl *et al*., 2012). Additionally, an unclassified chitinase (g481), a chitin deacetylase (g374), and a cell wall glycoprotein (g280) involved in carbohydrate metabolism were found. Two proteins, involved in fungal cell wall catabolic process, were also identified (g480 and g191). The position of these chitin catabolic proteins is really interesting as they are both located upstream to chitin metabolic proteins; g480 and g481 are encoded on contig 94 and g191 and g192 are located on contig 23.

A high proportion of predicted secreted proteins are potentially linked to the degradation of plant material (Table 25), for example g443 as cellulase, g442 as pectin lyase and enzymes involved in the modification of oligo- and monosaccharides (g342, g34, g247, g440, g14, g413, g256 and g203), phenol (g369) and lipid degradation (g277) were identified. Interestingly, cellulase g443 and pectin lyase g442 were found to be coded very closely on contig 92.

Three secreted proteins were predicted to be involved in adhesion (g400 and g92) and penetration (g262). G92 was similar to an agglutinin-like sequence (*Als2*) of *Candida albicans* that encodes a surface glycoprotein which is only expressed during infection (Hoyer *et al*., 1998) while the closest hit of g262 was Cas1, an appressorium specific protein that is expressed during appressoria formation of *Colletotrichum higginsianum* (Bakar *et al*., 2006). Two proteins were predicted to have hydrolase activity (g343 and g209), two proteins with protein-binding functions

(g471 and g411) in addition to three proteases (210, g197 and g199) and an amino acid oxidase (g156), and one protein (g416) was associated with antibiotic resistance that could be involved in plant material degradation and also in defence (Michielse *et al*., 2006, Rooney *et al*., 2005). A significant proportion (22%) of the proteins was identified as hypothetical proteins.

Ten predicted proteins were chosen for further analysis based on their nucleotide similarity to other proteins available on NCBI database (NCBI) and to genome sequences of formae speciales available on Broad Institute's database (Broad Institute) (Table 25). Nucleotide sequence similarity of chosen proteins varied between 47%- to 70%, while amino acid sequence similarity diverged between 47%- to 90%, predicted amino acid length was between 413-1818 amino acids and number of cysteines varied between 1- to 50 (Table 25). Five genes of Fus2 (*g481, g480, g191, g192, g374*) linked to chitin synthesis and degradation/modification were chosen for further analysis to be screened for their presence among 21 *F. oxysporum* isolates. *G48*0 and *g481* were only present in a few FOC isolates. In contrast, *g374, g191* and *g192* were present in the majority of FOC isolates (*g191* and *g192* was absent in isolate SM54) and some other formae speciales such as *medicaginis* and *asparagi*. Primer pairs were designed (Table 26) to amplify selected proteins from 21 *F. oxysporum* isolates representing six formae speciales and isolates with undefined host-specificity. Presence or absence of products was recorded and where it was possible isolates were divided into sequence type groups based on their sequence similarities (Table 27).

Two proteins showing similarity to glucooligosaccharide oxidase (*g342*) and para-nitrobenzyl esterase (*g256*) were chosen for further analysis based on their similarity to published sequences. *G342* was only found in some of the isolates, including representatives of *F. oxysporum* formae speciales *cepae*, *asparagi* and isolates non-aggressive in onion seedlings and it was identical in all isolates. Para-nitrobenzyl esterase-like gene (*g256*) was present in most of screened isolates (except A14, NL70_7, 22 and NRRL26222). Five *g256* sequence types were observed among 21 isolates, although A was the most common (Table 27).

Several of the screened candidate effector genes were limited to three or four isolates (Table 27). For example, isolate Fus2, Fus3 and 25 had all the candidate effector genes, and SP7-2 had all except two (*g342* and *g343*). Candidate effectors *g256, g374, g471, g191* and *g192* were present in highly aggressive isolates. Some candidate effectors seemed to show more variation than others: *g463* had seven sequence types (A – G), *g256* and *g192* comprised five (A – E), *g191* contained four (A – D), *g374* and *g471* three (A – C) and *g342, g343, g480* and *g481*comprised only one sequence type (A). In general, the higher number of candidate effectors detected in the genome of an isolate the more likely it was to be very aggressive in onion seedlings.

Sequences of the candidate effectors gene *g463* correlated with the results of the onion seedling assay. Sequence types A, B and E of *g463* could be promising to identify FOC as they were only present in very aggressive *F. oxysporum* isolates, while sequence types C, D, F and G were found in *F. oxysporum* isolates non-aggressive in onion seedlings (Table 27).

The genome sequences of ten additional *F. oxysporum* isolates became available in November 2011 from the Broad Institute, which allowed the screening of these isolates for the presence of candidate effector genes selected primarily in this work (Table 28). The only candidate effector which lacked any homologues was *g256,* while *g342, g343* and *g374* had one homologue each, *g480* and *g481* had two homologues each, *g463* and *g471* had seven homologues each, and *g193* had nine homologues.

Hosts of isolates: *Pisum* (*pisi*), *Brassica/Arabidopsis* (*conglutinans* race2), *Solanum lycopersicum* (*radicis-lycopersici*, *lycopersici* race2 and race3), *Homo sapiens* (human), *Gossypium* (*vasinfectum*), *Raphanus/Arabidopsis* (*raphani*), *Musa* (*cubense* race 4), *Cucurbita* (*melonis*)
**lycopersici* race 2 4287 and mitochondria were used for the original template based assembly

None of the candidate effectors had a hit against *melonis*, *lycopersici* race 2 and mitochondrial genomes (Table 28), which suggests that the template based assembly was applicable to identify all homologues. Moreover, it reveals that lineage specific regions are present in *pisi* (four hits), *radicis-lycopersici* (four hits), *conglutinans* race2 (three hits), *lycopersici* race3 (three hits), *vasinfectum* (two hits), *raphani* (two hits), *cubense* race 4 (two hits), human pathogenic (three hits) and even in the biocontrol strain Fo47 (three hits).

SUMMARY

Genome sequence analysis revealed that there are at least 509 genes present in the genome of FOC Fus2 which are not present in the genome of tomato pathogen FOL 4287, such as pisatin demethylase. In total, 40 proteins of Fus2 were predicted to possess N-terminal signal peptide. These secreted proteins are predicted mainly to

be involved in the degradation of plant material (29%), chitin synthesis/metabolism (20%) or have unknown function (22%). In total eleven candidate effector genes of FOC were tested on a set of 20 *F. oxysporum* isolates from diseased *Allium* species and different formae speciales. The presence / absence of eleven candidate effector genes of Fus2 suggests that the more of these genes that are present in a *F. oxysporum* strain the more likely it is to be more aggressive in onion seedlings. One candidate effector gene with unknown function of Fus2 was found promising for the specific identification of FOC isolates based on this preliminary data. This gene was *g463.*

4.4.4 Annotation of genes of Fus2 without N-terminal secretion signal peptide

Proteins were annotated using Blast2GO (Conesa *et al.*, 2005) and about 25% of these predicted proteins could not be functionally classified on the basis of homology to known proteins (Appendix VI). The rest of the genes were involved in the degradation of plant cell wall, translocation of metabolites, synthesis of enzymes, polyketides, small signalling proteins, transcription factors, proteins involved in fungal growth and pathogenicity. There are a number of proteins predicted to have role in fungal pathogenesis, such as pisatin demethylase enabling the infection of pea by degrading phytoalexin pisatin (Temporini and VanEtten, 2004).

One of the most striking observations is the discovery of enzymes involved in the synthesis of various toxins in the genome of Fus2, including mosquitocidal toxin, aflatoxin and trichothecene. Mosquitocidal toxins are pore-forming protein toxins and were described originally from *Bacillus sphaericus* as insecticides (Maagd *et al*., 2003). A ketoreductase, nor-1, was identified, which is involved in aflatoxin

synthesis in *Aspergillus* species (Zhou and Linz, 1999). Trichotechene production requires the presence of several genes, however only trichothecene 3-o-acetyltransferase and tri15 were identified.

The closest homologue of some of the predicted proteins generally occurs in plants and animals. A protein which is normally found in plants was gibberellin-3β-hydroxylase, involved in the synthesis of plant hormone gibberellin (Cadman *et al*., 2006). A glycoprotein similar to von Willebrand factor, which is involved in adhesion to wound sites in mammals (Ruggeri and Ware, 1993), was also predicted.

A homologue of a reverse transcriptase was also found; active reverse trascriptases were found on two linear mitochondrial chromosomes or mitochondrial retroplasmids of *F. oxysporum* (Kistler *et al*., 1997, Simpson *et al.,* 2004). Two proteins involved in vegetative compatibility were also predicted in Fus2. Interestingly, two very common vegetative compatibility groups (VCGs) and several less frequent VCGs have been found within FOC (Southwood *et al.,* 2012).

4.4.5 Evaluation and test bioinformatics tools and markers for the identification of further effector genes

In the genome of Fus2 by an *in silico* screening using contigs published in PHI-BASE database of 15 pathogenicity genes were identified (Table 27) (Winnenburg *et al*., 2008).

All 15 of these genes were coded on the “core” genome (core genome defined by Ma *et al*, 2010) of FOL4287 unlike the four *SIX* genes coded on the “lineage specific” region (Table 29). Eleven pathogenicity genes of FOL4287 showed a high level of amino acid similarity (<98%) to the homologues of Fus2. In contrast, *ARG1*,

FMK1, FOW1, and *FOXG_00016* shared 87, 92, 89 and 87% amino acid similarities, respectively.

Table 29. Location and similarity of 15 pathogenicity genes in the genomes of *Fusarium oxysporum* f. sp. *lycopersici* 4287 (FOL) and *F. oxysporum* f. sp. *cepae* Fus2 (FOC).

Gene	Description	FOL4287	Similarity*	FOC Fus2

*using tBLastx algorithm, FOL: Chromosome of FOL4287, FOC: Contig of Fus2

Contigs harbouring *SIX3, SIX5* and *SIX7* were screened for mimp elements in their promoter region to test whether it can be useful marker for the identification of additional *SIX* genes. This screening revealed the presence of a mimp element in the promoter of *SIX7*, but not *SIX3* or *SIX5*, although the contig where *SIX5* was found is very short and may not cover the entire promoter region. This indicated that the presence of mimp elements in the promoter region of candidate genes could be a

useful marker for the identification of some *SIX* genes in the genome of Fus2. All 1511 contigs of Fus2 were screened for the presence of mimp elements which identified 61 mimps in this genome. These 61 contigs can be subjected to annotation and based on the location of mimp elements additional *SIX* genes could be predicted.

SIX3, *SIX5* and *SIX7* harbouring contigs were compared which led to the identification of a short (34bp) identical sequence downstream (3' prime end) of the coding regions of *SIX5* (NODE_1095) and *SIX3* (NODE_11538). A 19 bp long region (CCGCGTTGAGGTTTTCCCA**)** of this sequence showed 100% similarity a crinkler (CRN) protein (GENE ID: 9477723 PITG_00601) of *Phytophthora infestans*.

A novel motif L[HF][HS][HS]A was found among the secreted proteins by MEME v. 4.8.1 (Baily *et al*., 2009). This motif was present in four proteins out of 41, namely g484, g14, g473 and g346. Leucine-rich nuclear export signals (NES) were predicted by the NetNES 1.1 server among secreted proteins (la Cour *et al*., 2004) (Table 30).

Table 30. Leucine-rich nuclear export signal containing secreted proteins of Fus2 and amino acid sequences of corresponding signals.

Predicted secreted protein	Leucine-rich nuclear export signal
Contig_92_g444	LLDGHLPV
Contig_66_g374	LAADKLLSPL
Contig_47_g333	VGKDLEALEL
Contig_40_g280	LAGAIGAAAVAL

Forty-one secreted proteins of FOC not present in the genome of FOL were screened for the presence of published motifs (Appendix VIII). RXLR motifs were found in four proteins (g343, g413, g463 and g470), dEER in five proteins (g191,

g192, g256, g416, g470), Y/F/WxC in 14 proteins (g14, g71, g191, g192, g197, g247, g262, g277, g333, g374, g401, g470, g480, g481), HaRxLs in three proteins (g199, g203, g416), DWL in three proteins (g411, g443 and g470), [L/I]xAR in three proteins (g191, g369 and g470). [R/K/H]x[L/M/V/F/Y/W]x was present in all proteins except three (g262, g280 and g51). In contrast LFLAK, [R/K]CxxCx12H, G[I/F/Y][A/L/S/T]R and YxSL[R/K] were not found in any of the proteins.

SUMMARY

The use of bioinformatics tools/database/markers was explored for the *in situ* identification of (candidate) effector genes in the genome of FOC.

PHI-BASE (Winnenburg *et al*., 2008), a database of previously published pathogenicity genes was searched for genes identified in *F. oxysporum* formae speciales *lycopersici* and *pisi*. In total, 15 genes were identified and were exploited to further analysis. Among these, homologues of four (*ARG1*, *FMK1*, *FOW1*, and *FOXG_00016*) were showing lower (87-92%) sequence similarity, therefore could be useful to further investigate their use in FOC-specific molecular test).

Previously, it was shown that mimp elements in the promoter region of candidate genes could be a useful marker for the identification of *SIX* genes (Schmidt, 2012). Mimp element was identified in the promoter of *SIX7* of FOC, but not *SIX3,* therefore this marker is only useful for the identification of some candidate effector genes in the genome of FOC. Additionally, multiple sequence alignment of *SIX3, SIX5* and *SIX7* harbouring contigs of FOC led to the identification of an identical (34bp) sequence upstream the coding region, which showed also seems to present in a Crinkler protein of *P. infestans*.

Four secreted proteins were predicted to comprise leucine-rich nuclear export signals (NES) by the NetNES (la Cour *et al*., 2004). A novel motif was found among the secreted proteins by MEME v. 4.8.1 (Baily *et al*., 2009). Ten previously published motifs present in various effectors were identified by a Python script (Holmes, 2012) among secreted proteins.

4.5 DISCUSSION

4.5.1 Preparation of DNA sample and genomic library for genome sequencing of FOC

To date twelve genome sequences of *F. oxysporum* have been published (Broad Institute, Thatcher *et al.,* 2012). The genome sequence of Fus 2 provides a novel resource to enhance our understanding of the *F. oxysporum* – non-model plant interaction. Previously published plant pathogenic *F. oxysporum* strains typically cause wilt disease, therefore the sequence of a root and bulb rot causing strain, FOC, could be useful to have a better understanding of formae speciales causing these symptoms. Some rot causing *F. oxysporum* formae speciales colonise only the cortex, some both cortex and xylem (Baayen and Rijkenberg, 1999, Baayen *et al.*, 2000).

Genome sequencing requires good quality (i.e. unsheared) DNA extract to obtain large insert libraries. Therefore CTAB method was chosen to extract a large amount of DNA of FOC strain Fus2. This primary extract contained high amounts of fairly pure DNA, therefore it was considered as a suitable method for the preparation of genomic libraries. This primary extract was RNase treated and further purified by QIAEX kit (Qiagen). This kit binds DNA to beads instead of filters during the purification process, therefore in theory these results in a least sheared DNA sample. Unfortunately, this kit gave at least x20 diluted DNA sample by the end of the purification compared to the CTAB extract. A recent protocol by the 1000 Fungal Genomes Project suggested the use of a modified version the protocol of Fulton *et al.* (1995) with the combination of Qiagen genomic tip 500/G which would have been a solution for the clean-up phase (1000 Fungal Genomes Project). Some publications

reported that commercially available genomic DNA extraction kit gave DNA applicable for genome sequencing (Tom Hsiang, University of Guelph, pers. comm.).

4.5.2 *In silico* analysis pipeline based on *de novo* assembly to identify putative effectors from the genome of Fus2

The estimated size of Fus2 genome was 49.99 Mb which is smaller compared to the 61.36 Mb genome of FOL4287, but on average (46.55 Mb – 55.18 Mb) compared to the ten other *F. oxysporum* genomes sequenced by the Broad Institute.

The first effector gene, *SIX1*, of FOL was cloned in 2004 by Rep and co-workers (Rep *et al*., 2004) and to date in total 15 *SIX* genes have been discovered in the genome of FOL (Takken and Rep, 2010; Sarah Schmidt, University of Amsterdam, pers. comm.). Only the roles of *SIX1* (=*AVR3*), *SIX4* (=*AVR1*) and *SIX3* (=*AVR2*) have been confirmed (Rep *et al*., 2004; Houterman *et al*., 2008; Houterman *et al*., 2009). Homologues of *SIX6*, *SIX7*, *SIX8*, *SIX9*, *SIX1* (=*AVR3*) and *SIX4* (=*AVR1*) has been reported from *F. oxysporum* ff. spp. *lilii*, *melonis*, *radicis-cucumerinum*, *vasinfectum* and *Arabidopsis*-infecting strain Fo5176, respectively. *In silico* screening of the Fus2 genome led to the discovery of the homologues of *Foc-SIX3*, *Foc-SIX5*, *Foc-SIX7* and *Foc-SIX9*. This is the first report of the discovery of a homologue of *Fol-AVR2* (=*Fol-SIX3*) and *Fol-SIX5* in FOC, another f. sp. than FOL. The *SIX3* gene was thought to be unique to FOL (Takken and Rep, 2010). The *SIX3* homologue shows considerable (86%) amino acid differences. This suggests that the *SIX3* gene of these two formae speciales was not recently gained. For example, the homologue of *SIX4* (=*AVR1*) was found in an *Arabidopsis*-infecting strain Fo5176 which differed in only two amino acids when compared to the *SIX4* of FOL (Thatcher *et al*. 2012). The high level of conservation was proposed to be caused by

recent gain of this gene from a common ancestor. The other possibility is that the *SIX3* gene of FOC is under strong selection pressure to adapt to its host. The presence of homologues *SIX3* in the genome of FOC might indicate the presence of the corresponding resistance gene (*I-2*) of tomato in the onion genome. As no onion genome sequence available at the moment it could be investigated by hybridisation and by designing degenerate primers on resistance gene *I-2* of tomato.

Nine genes were predicted on the contig containing *SIX3* which showed similarity to hypothetical proteins and active transposable elements. This agrees with previous findings; lineage specific regions of FOL4287 were rich in transposable elements and most of the predicted proteins were uncharacterised (Ma *et al*., 2010). Strikingly, *Fol-SIX3* and *Fol-SIX5* are coded in close proximity, but not their homologues in the genome FOC Fus2. This rearrangement is very likely to be the result of transposon activity. For example, a novel biotype of FOL race 3 isolate was found that had *AVR1*, but it was gene truncated by the transposon, mobile genetic elements were proposed to be the driving forces underlying race evolution (Inami *et al.*, 2012). Three active transposable elements were predicted on the contig coding *SIX3* of FOC. It was impossible to functionally characterise a non-secreted short protein (g5), which is a characteristic of *SIX* genes (Rep *et al*., 2004; Houterman *et al*., 2008).

Screening of 75 FOL isolates representing all three races for the presence of *SIX1-SIX7* genes revealed that *SIX1-SIX3* and *SIX5-SIX7* were present in all FOL isolates, while *SIX4* was present only in FOL race 1 (Lievens *et al*., 2009a). Moreover, sequences of individual *SIX* genes were identical for all FOL isolates. In contrast, *SIX3, SIX5 and g5* were not found in all *F. oxysporum* isolates very aggressive in onion seedlings, although these genes were found conserved in those

aggressive isolates tested positive for their presence. This high level of conservation suggests that these genes have an evolutionary conserved function that constrains gene diversification. The presence of identical sequence type of *SIX5* in some of the isolates tested as weakly and very aggressive in onion seedlings could suggest that these isolates have similar host range or way of infection.

Overall, *SIX3*, *SIX5* and *g5* are useful for the robust identification of some of the very aggressive FOC isolates, although some FOC isolates seem to lack these genes therefore further markers are needed to identify the "*SIX*-negative" FOC isolates. However, it is also possible that some of the *SIX* genes are present in these isolates, but did not amplify due to variation in *SIX* gene regions targeted by primer used. Genome sequencing of these isolates or hybridisation could help to clarify this. It is still useful information that homologues of *SIX3* (=*AVR2*) and *SIX5* are present in both FOL and FOC.

Expression analysis of these genes *in planta* is also needed and phenotypic analysis of deletion and overexpressing mutants to clarify the role of these genes in FOC. In case Foc-*SIX* genes are functioning and differentially expressed *in planta* that could suggest that FOL and FOC are using similar mechanism to manipulate host cells.

4.5.3 *In silico* analysis pipeline based on template based assembly to identify candidate effectors in the genome of Fus2

Genome sequence based assembly identified reads which showed high similarity to the template (FOL4287) and left aside the unmatched reads. In theory, the unmatched reads correspond to unique genomic regions, which do not occur in the "core *Fusarium* genome" (regions present in *F. verticillioides, F. graminearum* and *F. solani*) or in the *lycopersici*-specific lineage specific regions (Ma *et al*., 2010). The unmatched (presumably including FOC-specific) reads were assembled using *de novo* assembly which resulted in 85 contigs. This approach hugely narrowed down the amount of data to be analysed further not to mention the time and computational power required. This approach could be further developed by using other *F. oxysporum* genome sequences (being) published as templates to identify unique regions of Fus2.

In total, 509 proteins were predicted over the 85 contigs of Fus2 which do not show similarity to those encoded in the genome of FOL4287. In total 17,708 genes were predicted from the genome of FOL4287 excluding the mitochondrial genome (Broad Institute). This again, shows that the combination of template based and *de novo* assembly hugely reduced the number of genes to be analysed. These 509 genes could be the key to finding what makes a *F. oxysporum* isolate aggressive in onion seedlings rather than tomato. These proteins could be interacting with the plant directly or indirectly in the same time (Aslam *et al*., 2009). It is also possible that some of these genes are pseudogenes (Campbell *et al*., 2012). The accuracy of gene prediction could be improved by using the combination of several gene prediction software packages such as FGENESH (Softberry) and / or by "training" these prediction programs by using *F. oxysporum* EST data (Stanke *et al*., 2008).

In total, 42 out of 509 proteins were predicted to encode N-terminal signal peptides and only one of them was predicted to be a transmembrane protein. These results show that the latest version of SIGNALP program provides a fairly good prediction, but the employment of TMHMM is very valuable to improve prediction of secreted proteins. It also has to be considered that there are independent ways of protein transportation which do not involve the presence of N-terminal signal peptides (Ridout *et al*., 2006). For example, the RXLR-dEER motif of *Phytophthora* fused with GFP protein can be transported into plant cells (Dou *et al*., 2008). Moreover, there are *in silico* tools already available to predict "non-classical" secreted proteins of bacteria and mammals (Bendtsen *et al.,* 2005).

In total, 41 secreted proteins were predicted over these 85 contigs of Fus2. These are predicted to be involved in the degradation of plant material, proteolysis, chitin synthesis/metabolism and defence, pathogenicity or have unknown function. The majority (29%) of the 41 secreted proteins were annotated to be involved in the degradation of plant material (cellulose, pectin, oligo- and polysaccharides). One protein was found to be involved in the degradation of phenolic compounds, which could indicate its role in lignin (phenolic polymer) or toxic phenolic compound degradation (Michielse *et al*., 2009). Only 20 % of the genes encoded on the lineage specific region of FOL4287 could be functionally classified, but some of the annotated genes were secreted enzymes predicted to degrade or modify plant or fungal cell walls (Ma *et al*., 2010). Pectic enzymes, exo-polygalacturonase and endopectin-trans-eliminase of FOC, were observed in the onion stem at the beginning of colonization (Holz and Knox-Davies, 1985). It is possible that some of these proteins also assist the saprophytic lifestyle to utilize decaying plant material (Kim *et al*. 2007).

Two proteins showing similarity to glucooligosaccharide oxidase (g342) and para-nitrobenzyl esterase (g256) were chosen for further analysis based on their similarity to published sequences. G342 was only found in a few isolates and it was identical in all isolates, which either means that this gene was gained recently from a common origin or it has a conserved function. In contrast, para-nitrobenzyl esterase-like protein (g256) was present in most of screened isolates and showed sequence variation. In general, none of these genes aligned with aggressiveness in onion seedlings.

Relatively large proportions (20%) of secreted proteins were predicted to be involved in chitin synthesis or degradation. Chitin is one of the most important fungal pathogen-associated molecular patterns (PAMPs) which can be recognized by plants and mammals and can trigger the immune response (Vega and Kalkum, 2011). In rice, the chitin elicitor binding protein (CEBiP) recognizes chitin oligosaccharides released from the cell walls of *M. oryzae,* which overcomes PAMP-induced immunity by secreting an effector protein, secreted LysM Protein1 (Slp1) (Mentlak *et al*., 2012).

Chitin synthesis has been shown to be crucial for pathogenicity; several chitin synthase gene knock-out mutants lost virulence or had reduced virulence (Martinez-Rocha *et al*., 2008; Martin-Urdiroz *et al*., 2008). Proteins involved in chitin synthesis of FOC are predicted to be secreted, which disagrees with previous findings; known chitin synthases are not integral membrane-bound proteins (Roncero *et al*., 2002). The role of chitinases in terms of virulence has not been proved in *F. oxysporum*, although they were detected by insertional mutagenesis as potential pathogenicity related genes (Michielse *et al*., 2009). Chitinase mutants of *Aspergillus fumigatus* showed only a limited reduction in the total chitinolytic activity and had no growth

or germination defects (Alcazar-Fuoli *et al*., 2011). The presence of genes linked to chitin synthesis and their utilization is crucial in the process of cell wall remodelling to respond to host defence (Michielse *et al*., 2009). Also, some of the secreted enzymes modify pathogen cell walls, e.g. chitin deacetylase, in order to protect themselves from enzymatic hydrolysis (El Gueddari *et al*., 2002). An avirulence protein of *C. fulvum,* Avr4, contains a chitin-binding motif which protects the fungal cell wall from plant chitinases (van den Burg *et al*., 2006). Interestingly, some of the chitin catabolic genes (*g191* and *g480*) of Fus2 were encoded upstream of chitin metabolic genes (*g192* and *g481*), suggesting that their regulation is linked, which would allow for the continuous remodelling of fungal cell walls. Four genes (*g481, g480, g191, g192*) linked to chitin synthesis and degradation along with chitin-deacetylase (*g374*) of Fus2 were chosen for further analysis. *G480* and *g481* were only present in a few FOC isolates suggesting that they might be "accessory" genes of FOC isolates. In contrast, g191 and g192 were present in the majority of FOC isolates (except SM54) and some other formae speciales such as *medicaginis* and *asparagi*. Wheat pathogen *Mycosphaerella graminicola* has eight small accessory chromosomes which have a role in host adaptation (Stukenbrock *et al*., 2010). G374 was present in all FOC isolates and in a few additional isolates, which suggest that chitin-deacetylase is essential for pathogenicity in onion. Unfortunately, none of the sequence types of *g481, g480, g191, g192* and *g374* aligned with pathogenicity.

Two proteins were predicted to have hydrolase activity (g343 and g209). Hydrolases were predicted from *F. graminearum* secretome (Brown *et al*., 2012; these proteins could be involved in the degradation / modification of plant or fungal material and tissue maceration. Amidohydrolase *g343* was chosen for further analysis based its low sequence similarity to known proteins. It was detected in

several highly and non-aggressive *F. oxysporum* strains and its sequence was highly conserved, which suggests that this protein has a recent common origin. Unfortunately the presence of *g343* did not correlate with pathogenicity.

Two proteins were predicted to have protein-binding function (g471 and g411) additionally to three proteases (g210, g197 and g199) and an amino acid oxidase (g156) that could be involved in plant material degradation and also in defence (van der Hooven *et al*., 2001; Michielse *et al*., 2009). Genes linked to protein degradation, translocation and amino acid metabolism were found to be important in pathogenesis of *F. oxysporum* (Michielse *et al*., 2009). Also, proteinases are commonly found to be involved in cell defence. For example, Avr-Pita effectors from *M. oryzae* show homology to zinc-dependent metalloproteases (Jia *et al.,* 2003). A metalloproteinase (mep1) was described from the human pathogen *Coccidioides posadasii* that digests an immunodominant cell surface antigen and prevents host recognition of endospores (Hung *et al*., 2005). A secreted metallopeptidase was found to be expressed exclusively during the infection of wheat by *F. graminearum* (Paper *et al*., 2007). An entire class of Kazal-like extracellular serine protease inhibitors directly interacting with and inhibiting host proteases was described from *P. infestans* (Tian *et al*., 2005). AvrP123 of *M. lini* contains a Kazal serine protease inhibitor signature which suggests that it has a role in the inhibition of host proteases (Catanzariti *et al*., 2006). *G471* was chosen for further analysis as its presence of an ankyrin repeat suggests that it is involved in protein-protein interaction. This protein was found in almost all very aggressive isolates and a few non-aggressive isolates including *F. oxysporum* ff. spp. *medicaginis* and *asparagi*. Three sequence types were observed but there was no relationship between aggressivess in onion seedlings.

Three proteins were predicted to be involved in adhesion (g400 and g92) and penetration (g262) based on sequence similarity. In an isolate of *F. oxysporum* which infects tomato, localized hyphal swellings were observed which may represent appressorium-like penetration structures (Czymmek *et al*., 2007). A set of *F. oxysporum* isolates will be screened for the presence of these proteins in order to establish a better understanding of their pathogenicity and to investigate whether or not they differ between isolates.

A high proportion (22%) of the proteins was identified as hypothetical proteins, which agrees with previous findings. Half of the *F. graminearum* secretome encoded for proteins of unknown function (Brown *et al*., 2012). Moreover, 80% of the genes encoded on the lineage specific regions of FOL4287 could not be functionally classified (Ma *et al*., 2010). A conserved hypothetical protein (FOXG_09487) was verified by reverse genetic approaches and shown to be important for *F. oxysporum* pathogenicity (Michielse *et al*., 2009). One candidate effector gene, *g463*, without functional classification of Fus2 was chosen for further analysis. Preliminary data based on the screening of 21 *F. oxysporum* isolates representing various formae speciales suggests that some of the sequence types (A, B and E) could be linked to pathogenicity. The sequence variation within *g463* can be due to diversification, which would imply that the target of g463 in onion is also changing and under selection pressure (Allen *et al*., 2004). The screening of *g463* needs to be tested on a broader range of isolates to prove this theory.

In summary, the presence / absence of ten candidate effector genes of Fus2 suggests that the more of these genes are present in a *F. oxysporum* strain it is the more likely to be aggressive in onion seedlings. Collectively these genes may represent the conserved and unique protein-protein and protein-substrate interactions

that assist *F. oxysporum* pathogenicity. PCR-based screening of ten candidate effector genes of Fus2 revealed that *F. oxysporum* ff. spp. *medicaginis* and *asparagi* may have similar lineage specific regions than formae speciales *lycopersici, gladioli* and *dianthi*. Screening the genomes of eleven *F. oxysporum* representing several formae speciales revealed that homologues of ten candidate effector genes of Fus2 are more frequently present in formae speciales *pisi*, *radicis-lycopersici* and *conglutinans* than eight other formae speciales. Formae speciales containing similar sets of candidate effectors are probably using similar strategies to modify host cell structure and function for their advantage. To clarify this, it would be useful to test host specificity of Fus2 strain on a variety of plants, such as *Arabidopsis*, pea, tomato, alfalfa and asparagus. Also, the analysis of these genes *in planta*, so as the disruption and overexpression mutants, is necessary to clarify if they are involved in pathogenicity. This study contains only preliminary results as only ten out of 41 genes were further investigated. Among the remaining 31 genes there are promising candidates that could be useful for further investigations. Additionally, genome sequencing of additional FOC isolates, preferably some of those tested negative for the presence of *SIX* genes, would be highly valuable to identify effectors specifically present in FOC.

4.5.4 Annotation of genes of Fus2 without N-terminal secretion signal peptide

Annotation of 509 genes not present in *F. oxysporum* f. sp. *lycopersici* reveal those are involved in the degradation of plant cell wall, translocation of metabolites, synthesis of enzymes, polyketides, small signalling proteins, transcription factors, proteins involved in fungal growth and pathogenicity. The presence of two non-

secreted proteins predicted among these is particularly interesting. One of them is pisatin demethylase (found in two copies in the genome of Fus2), a protein involved in the detoxification of antifungal pisatin toxin produced by pea plants. This gene was found in *F. solani* and *F. oxysporum* f. sp. *pisi* encoded on small chromosomes and the transfer of this gene into *F. oxysporum* f. sp. *lini* promoted pathogenicity on pea (Coleman *et al*., 2011ab). Further homologues of pisatin-demethylase were found in *F. oxysporum* ff. spp. *dianthi, lini, glycines* and *phaseoli*, but only the one from the bean-pathogen was functioning (Coleman *et al*., 2011ab). These results suggest that this gene was gained through horizontal gene transfer by FOC. It has to be investigated if pisatin demethylase of Fus2 is functioning.

Another gene is gibberellin-β-hydroxylase, which is involved in the synthesis of plant hormone gibberellin. *F. sacchari, F. konzum* and *F. subglutinans* were reported to synthesize gibberellins (Troncoso *et al*., 2010). Gibberellin is a plant hormone involved in the utilisation of starch in germinating seeds and in regulation of sugar signalling pathway (Cadman *et al*., 2006). It was proposed that phytopathogenic bacterium *Xanthomonas oryzae* pv. *oryzae* used effectors to upregulate the transcription of *SWEET* (sucrose effluxer) genes of rice to increase sugar efflux into the apoplast (Chen *et al*., 2012). This could suggest that FOC might be capable of manipulating host-cell sugar metabolism for its advantage.

Several genes involved in toxin production were found, however most of these genes are part of a gene cluster (Zhou and Linz, 1999), therefore individual appearance does not indicate that these toxins (aflatoxins and trichothecenes) would be produced by Fus2. Moreover, *Tri15* is *a* negative regulator of at least some of the trichothecene biosynthetic genes (Alexander *et al*., 2004) and trichothecene 3-o-acetyltransferase is able to modify trichothecenes and reduce their toxicity (Khatibi

et al., 2011). This suggests that Fus2 is capable of competing against trichotechene producing fungi. Some entomopathogenic fungi, such as *Metarhizium anisopliae* and *M. acridum* are capable of producing mosquitocidal toxins (Gao *et al*., 2011). Culture filtrates of *F. oxysporum* and spore treatment by *F. pallidoroseum* were able to control tropical disease vector mosquitos (Singh and Prakash, 2011; Mohanty *et al*., 2008).

A reverse transcriptase was also predicted from the genome of Fus2. It is very likely that this reverse transcriptase is the one found on mitochondrial chromosomes of *F. oxysporum* previously (Kistler *et al*., 1997). The latest research suggests that this reverse transcriptase is capable of utilizing RNA, DNA and protein primers and was suggested to be an evolutionary precursor of a broad range of retroelements, including hepadnaviruses, non-long terminal repeat (non-LTR) retrotransposons and telomerase (Galligan *et al*., 2011).

Two heterokaryon incompatibility proteins were predicted, which is not too surprising as several VCGs of FOC have been found (Southwood *et al*., 2012). The surprising finding is that one of them is actually encoded closely to one of the pisatin demethylase genes. This could suggest that VCGs are useful to distinguish host specific forms of *F. oxysporum*.

These preliminary results suggest that there is key information in terms of host specificity hidden under the avalanche of genome sequence data. For example the presence of pisatin demethylase in the genome of FOC is a sign that FOC could potentially cause diseases on peas or maybe even other legumes. The annotation of the whole genome would provide a better understanding of host-pathogen interaction within *F. oxysporum*.

4.5.5 Evaluation and test bioinformatics tools and markers for the identification of further effector genes

Five pathogenicity genes, *ARG1, FMK1, FOW1*, and *FOXG_00016* of *F. oxysporum* ff. spp. *lycopersici* and *phaseoli,* listed in PHI-BASE database (Winnenburg *et al*., 2008) showed low amino acid similarities to FOC, therefore they could be good candidates for its specific identification. The PHI-BASE have not been updated since 2006, therefore the screening of pathogenicity genes published more recently is essential.

Also, the presence of mimp elements in the promoter region of candidate genes could be a useful marker for the identification of some *SIX* genes in the genome of Fus2.

Comparison of *SIX5* and *SIX3* encoding contigs led to the identification of a 19 bp identical region. It would be useful to investigate whether this short sequence present upstream from other candidate effectors.

A novel motif, L[HF][HS][HS]A, was found among four secreted proteins which could be a useful marker for the prediction of further effector genes one all genes predicted from the genome of Fus2.

Prediction of leucine-rich nuclear export signals (NES) could be extremely valuable as it could predict genes interacting with host nucleus. GFP-labelling of these proteins could clarify whether they target host nuclei.

The presence of motifs does not mean that they are functional; first their location has to be confirmed (N-terminal or C-terminal). For instant, the RXLR-like motifs, [R/K/H]x[L/M/V/F/Y/W]x, is possibly the most important published motif among all screened motifs in oomycetes. It was also demonstrated that RxLR-like motif exist in many fungal effectors including Avr2 (=Six3) of FOL and the motif is

proposed to play an important role in translocation of effectors into the host cell, through binding the phospholipid, phosphatidylinositol-3-phos-phate (PI3P) (Kale *et al*., 2010). However, recent work by Yaeno *et al*. (2011) suggests that PI3P binding of AVR3a of *P. infestans* is mediated by a C-terminal fragment lacking the RXLR domain.

This section showed that there are markers such as motifs and bioinformatics tools available to further characterize the proteome and secretome of FOC and also there are ways to predict ways of transport of effectors into host cell and also the location of the target molecules within host cell.

CHAPTER 5

INTERNAL FRUIT ROT OF SWEET PEPPER IN THE UK

5.1 INTRODUCTION

British sweet pepper (*Capsicum annuum* L.) production has doubled over the last ten years from about 10,000 to 20,000 tonnes with a cash value of £17M annually (Defra, 2011). In the UK, yellow and red varieties are grown mainly in greenhouses and immature green fruits are also sold (Tim O'Neill, ADAS, pers. comm.).

There are several fungal diseases causing economic losses for British sweet pepper growers such as *Phytophthora spp., Alternaria spp. Cercospora capsici, Leveillula taurica, Sclerotium rolfsii* and *Fusarium* species. Two different diseases are caused by *Fusarium* species on pepper fruits: stem and fruit rot and internal fruit rot (Figure 32).

Stem and fruit rot is caused by *Fusarium solani* (teleomorph *Nectria haematococca)* which gives black water-soaked lesions on the stem around the nodes and on the sides of the fruit (Jarvis *et al*., 1994, Fletcher, 1994, Lamb *et al*., 2000, Ramdial & Rampersad, 2010). This disease has been reported in Canada, United Kingdom, Trinidad, Hungary, Venezuela and New Zealand (Jarvis *et al*., 1994, Fletcher, 1994, Ramdial & Rampersad, 2010, Lukacs & Szarka, 1988, Cedeño *et al*., 2003). Contaminated rockwool cubes in which seedlings are grown could be a means of spread of stem and fruit rot of sweet pepper (Smudja, 1992). An increasing problem is internal fruit rot which was first reported in the early 2000s in Canada, Belgium, the Netherlands, the UK and Korea (Yang *et al*., 2009, Van Poucke *et al*., 2012, Choi *et al*., 2011).

Figure 32. Sweet pepper disease symptoms caused by *Fusarium* species. **A-B**. Symptoms of pepper stem and fruit rot (Photo credit: Cerkauskas, R., Agriculture and Agri-Food Canada). **A**. Black lesion around calyx. **B**. External and internal discoloration of stem. **C-D**: Symptoms of internal fruit rot of pepper (Photo credit: Yang, Y., University of Alberta). **C**. Pepper seeds are covered by mycelium. **D**. Brown discoloration of pepper fruit.

Unlike the stem and fruit rots, the symptoms are not as obvious as the rot starts from the inside of the pepper fruit with white mycelium covering the seeds and internal surface of the fruit. In a later stage, brown lesions can be seen on the outer surface of the fruit, which helps to remove the diseased fruits before marketing. Utkhede & Matur (2003) identified a *Fusarium subglutinans*-like fungus as the causal agent of internal fruit rot in 2003. Later, two groups reclassified the causal agent as *Fusarium lactis*, although *Fusarium proliferatum*, *Fusarium oxysporum* and *Fusarium solani* were also isolated from the same diseased fruits (Yang *et al*., 2009, Van Poucke *et al*., 2012). Van Poucke *et al*. (2012) showed that *F. lactis* isolates form a monophyletic clade, *F. lactis* species complex (FLASC), based on the translation elongation factor 1α (EF), β-tubulin (TUB), calmodulin (CAM) and the

second largest subunit of RNA polymerase II (RPB2) gene sequences. Twelve multi locus sequence types (ST1 to ST12) were defined within the *Fusarium lactis* species complex (Table 31). They also proposed that some of these isolates form a new, monophyletic species FLASC-1. *Fusarium lactis* causes fruit rot by infecting the flower through the transmitting tissues of the style and grows on the surface of the seeds (Yang *et al*., 2010).

Table 31. Genetic description of *Fusarium lactis* species complex multilocus sequence types (ST1 to ST12) from sweet pepper published by van Poucke *et al*., 2012.

[b] EF, translation elongation factor 1α gene.
[c] CAM, calmodulin gene.
[d] *RPB2*, second largest subunit of RNA polymerase II gene.
[e] TUB, β-tubulin gene.
[f] MAT, mating type *MAT1-1* or *MAT1-2*.
[g] ND: not determined.

It has been shown that some *F. proliferatum* and *F. lactis* isolates were able to produce limited amounts of the mycotoxin beauvericin and traces of fumonisin in pepper (Van Poucke *et al.*, 2012). Beauvericin was detected only in the lesions, while fumonisins were able to migrate to the surrounding, healthy tissue of the sweet pepper. There is a risk that diseased pepper fruits can be consumed as the symptoms are not always can be seen externally and therefore it is difficult to cull unhealthy fruits before delivery to market (Yang *et al*., 2011).

It is not clear how the disease spreads and measures recommended to reduce occurrence of Fusarium internal fruit rot include good sanitation practices, careful disposal of infected fruits and avoiding wounding of the fruit (O'Neill and Barbara, 2012). It has been shown that fusaria spore concentrations in the greenhouse air increased with higher temperature, humidity and radiation, therefore maintaining good air circulation and keeping the relative humidity below 85% helps to manage the disease. In Canada, bumblebees (*Bombus spp*.) are used as pollinators and these can also carry *Fusarium* spores (Yang *et al*., 2009). In the UK, pollinators are rarely used but fruits damaged by the tortrix moth caterpillar showed a high incidence of Fusarium rot (O'Neill and Barbara, 2012). Several chemical and biological treatments have been suggested to control internal fruit rot (Utkhede and Mathur, 2006). Flowers treated with iprodione, *Gliocladium catenulatum* or *Bacillus subtilis* had significantly higher fruit weight compared with controls. Resistant pepper varieties are not available, but varieties that produce small flowers appear more tolerant.

5.2 AIMS AND OBJECTIVES

Detailed aims and objectives of this chapter were:

- To obtain *Fusarium* isolates from sweet pepper
- To characterize isolates from sweet pepper fruit showing internal fruit rot symptoms at species level by using sequences of three molecular markers (*TEF*, *RPB2* and *CAL*)
- Compare sequence data of *Fusarium* isolates associated with internal fruit rot of sweet pepper obtained during this project with data previously published on this disease

5.3 MATERIALS AND METHODS

5.3.1 List of *Fusarium* isolates associated to fruit rot of pepper in the UK

Fusarium isolates (18) obtained from pepper fruit showing internal rot symptoms were characterised based on morphology on PDA by Tim O'Neill (ADAS) (Table 32, O'Neill and Barbara, 2012).

Table 32. Origin and morphology on PDA of 18 *Fusarium* isolates obtained from sweet pepper from three UK nurseries.

Isolate	Source of sample			Colour in culture on PDA

5.3.2 Molecular identification of *Fusarium* isolates obtained from sweet pepper showing internal fruit rot symptoms

DNA was extracted using a Qiagen DNeasy Plant Mini-kit with minor modifications as described in Section 4 (carried out by C. Grant, Warwick University). Three genes were used for the identification of *Fusarium* isolates: *TEF*,

calmodulin and RNA polymerase II subunit (*RPB2*). *TEF* targeting primers used were designed in-house (Table 7), while primer pairs amplifying *RPB2* and calmodulin were identical to those used in a publication (O'Donnell *et al*. 1998a, 2000, 2007). PCR reactions were as in Section 3.3.1.3 and sequencing of clean products was done as in Section 3.3.1.3.

5.3.2 Cladistic analysis of *Fusarium* isolates obtained from sweet pepper showing internal fruit rot symptoms

Sequence alignment and cladistics analysis was done as in Section 3.3.3.3. Additionally, for taxonomic reference *TEF* (26 sequences), calmodulin (19 sequences) and *RPB2* (17 sequences) sequences downloaded from NCBI were included in the cladistics analysis. Individual cladograms were produced based on *TEF, RPB2* and calmodulin sequences. Each cladograms contained sequences corresponding to a *F. lactis* type isolate recovered from fig fruit (Nirenberg and O'Donnell, 1998).

5.4 RESULTS

Fusarium species were not clearly distinguishable based on their morphology on PDA. Peach colonies were identified as *F. proliferatum* and *F. lactis*-like species, white colonies as *F. proliferatum F. solani* and *F. oxysporum*, purple colonies as *F. solani* and *F. lactis*-like species. Only the white/pinky-red colonies were identified uniformly as representatives of *F. oxysporum*.

Analysis of partial *TEF*, calmodulin and *RPB2* gene sequences led to the identification of *F. oxysporum* (6 isolates), *F. proliferatum* (3 isolates), *F. solani* (2 isolates) and *F. lactis* (7 isolates) species (Table 33). Analysis of partial *TEF*

sequences showed that *F. oxysporum*, *F. proliferatum* and *F. solani* isolates formed distinct clades which corresponded to the different *Fusarium* species used as taxonomic references. The topology of the *TEF* cladogram was confirmed by *RPB2* and calmodulin sequences (Figures 33 - 35).

British *F. lactis* isolates formed two clades, based on data from all three loci and showed high sequence similarity (>98%) to a type isolate recovered from fig fruit (Table 33). Six isolates (isolates 1-6) formed a distinct clade with some Belgian and Korean *F. lactis* isolates collected from sweet pepper showing internal fruit rot. Isolate 13 and a few Belgian isolates also formed a distinct clade. The presence of these two clades was confirmed by *RPB2* and calmodulin sequences.

All three isolates from pepper belonging to *F. proliferatum* were identical based on the sequence of all three molecular markers (Table 33). Similarly, there was no variation in sequence between British *F. lactis* isolates in clade 1 (isolates 1 - 6). Sequence comparison of our isolates to the isolates' used in a Belgian study (van Poucke *et al*., 2012) revealed that clade 1 corresponds to sequence type 1 (ST1) and clade 2 to ST7 defined by this group (Table 33). Several different sequence types were represented within clades corresponding to *F. oxysporum* and *F. solani*.

18.	B	White/pinky red	FO3	FO1	FO1	*F. oxysporum*

All isolates from fruit except isolate 9 (from a stem lesion).
TEF: TEF sequence group, RPB2: RPB2 sequence group, CAL: calmodulin sequence group
Sequence groups definition was adapted for *F. lactis* isolates from van Poucke *et al*. (2012).

Two isolates recovered from peppers grown in nursery A belonged to *F. proliferatum*, while all six isolates recovered from nursery C were identified as representatives of clade 1 within *F. lactis*. All four *Fusarium* species (including *F. solani* and *F. oxysporum*) were recovered from nursery B.

SUMMARY

Fusarium isolates (18) recovered from British sweet peppers showing internal fruit rot symptoms from three nurseries were identified based on partial *TEF*, calmodulin and *RPB2* gene sequences. This led to the identification of *F. oxysporum*

(6 isolates), *F. proliferatum* (3 isolates), *F. solani* (2 isolates) and *F. lactis* (7 isolates) species. *F. lactis* isolates formed two clades, based on data from all three loci and showed high sequence similarity (>98%) to a type isolate recovered from fig fruit. Sequence comparison of our isolates to the isolates' used in a Belgian study (van Poucke *et al*., 2012) revealed that clade 1 corresponds to sequence type 1 (ST1) and clade 2 to ST7 defined by this group. All three isolates from pepper belonging to *F. proliferatum* were identical based on the sequence of all three molecular markers, while several different sequence types were represented among *F. oxysporum* and *F. solani* isolates.

5.5 DISCUSSION

Internal fruit rot of sweet pepper appeared about ten years ago in the UK and has been an increasing problem since then (Tim O'Neill, ADAS, pers. comm.). As the symptoms are not always visible on the surface of the pepper fruit, it is difficult to cull diseased plants before they are marketed. A study in Canada revealed that the infection is caused by *F. lactis* which infects the flower following pollination (Yang *et al*., 2010).

The majority of the *Fusarium* isolates (seven out of 18 isolates) collected from pepper showing internal fruit rot symptoms were identified as *F. lactis*, which was reported as the principal cause of internal fruit rot in Canada and Korea (Yang *et al*. 2009, Choi *et al*., 2011). In an extensive study in Belgium, most of the isolates were identified as "*F. lactis*-like" species (van Poucke *et al*., 2012). The same study also included British, Belgian, Dutch and Canadian isolates from pepper and demonstrated significant genetic variation among the *F. lactis*-like isolates. Twelve sequence types (STs) were defined among *F. lactis*-like isolates and all three British isolates included in this study fell into ST1, the most common type. The majority of recently obtained isolates (isolates 1 - 6) also belonged to ST1, with one exception. A representative of ST7 (isolate 13) was recovered from nursery B. Presence of representatives of ST7 had not been reported from the UK previously. *F. lactis* was described as causal agent of endosepsis of fig in California (Nirenberg and O'Donnell, 1998) and since then these isolates are used as taxonomic references. Based on three loci (*TEF, RPB2* and calmodulin) our *F. lactis*-like isolates show at least 98% similarity to the type isolates from fig which shows high intraspecific variation, *i. e*. twelve multiple sequence types.

F. oxysporum was the second most common species isolated from British pepper showing internal fruit rot symptoms. Previous studies also detected *F. oxysporum*, but at a lower frequency compared to *F. lactis* (Yang *et al*., 2009, van Poucke *et al*., 2012). *F. oxysporum* has been reported in association with internal fruit rot and also with stem and fruit rot of British greenhouse pepper (O'Neill, 2008). The first symptom of wilting is usually yellowing of the leaves, which was not observed on plants with internal fruit rot. It is more likely that *F. oxysporum* is a secondary invader of the diseased fruit. The other possibility is that *F. oxysporum* also capable of infecting the plant through the flower, but this has not been tested.

A few *F. proliferatum* isolates were also present in British pepper showing internal fruit rot symptoms, which in in agreement with previous publications from Canada and Belgium (Yang *et al*., 2009, van Poucke *et al*., 2012). *F. proliferatum* is capable of causing "internal infection" on pepper fruits (Yang *et al*., 2009), but has not been reported in association with internal rot of sweet pepper from the UK previously.

F. solani was the least common species found on British sweet pepper showing internal fruit rot symptoms, which is in agreement with previous findings (van Poucke *et al*., 2012). *F. solani* was previously has been reported as the causal agent of stem and fruit rot of pepper in the UK (Fletcher, 1994). 18 years ago this disease affected less than 1 % of the crop in the UK, although, *F. solani* caused a more rapid external rot on pepper fruits (Yang *et al*, 2009).

Our isolates were collected from three nurseries (A, B and C) in the UK (same grower), but *F. lactis* was found to be dominant in only one of them (nursery C) and was not present at all in the sample from another nursery (A). The third nursery (B) had a very diverse community of *Fusarium* species. The present study is

based on 18 isolates, and hence only preliminary conclusions are drawn. More recent screening of aborted sweet pepper fruits suggested that *F. lactis* is the major cause of internal fruit rot in the UK (C. Grant, University of Warwick, pers. comm.).

Analysis based on colony morphology of isolates on PDA was unable to clearly distinguish different *Fusarium* species. Sequence analysis of housekeeping genes (*TEF, RPB2* and calmodulin) was necessary for the identification of *F. lactis* isolates as previous studies showed that *F. verticillioides*- and *F. subglutinans*-specific primers were not able to resolve the species level identification of *F. lactis* isolates.

This small study shows that methods developed for the identification of *Fusarium* species associated with *Allium* species could be employed to study other *Fusarium*-plant pathosystems such as internal fruit rot of sweet pepper. More importantly, the presence of *F. lactis and F. oxysporum* from sweet pepper showing internal fruit rot symptoms in the UK has been confirmed. Also, this is the first report of *F. proliferatum* and a new sequence type (ST7) of *F. lactis* in association with this disease in the UK. Sequence analysis of housekeeping genes proved to be a rapid and reliable method for identifying *Fusarium* species associated with internal fruit rot of sweet pepper.

CHAPTER 6

CONCLUSIONS AND FUTURE PROSPECTIVE

6.1 Conclusions

The *Fusarium* genus is taxonomically complex, and comprises a wide variety of filamentous fungi recognised as plant, animal and human pathogens and soil saprophytes. One of the most important member of this genus is *Fusarium oxysporum* Schlecht., includes plant pathogenic (formae speciales) and morphologically indistinguishable non-pathogenic forms that could act as disease suppressors, and it is not uncommon for both to co-exist in cropping-systems.

Allium and sweet pepper crops have been suffering more and more in recent years from diseases caused by *Fusarium* species in the UK. *F. oxysporum* f. sp. *cepae* was identified as causal agent of onion basal rot in the UK twenty years ago and causing increasing problems ever since then, while *F. lactis* was isolated from sweet peppers showing internal fruit rot symptoms only last year. Recent publications reported the co-existence of several *Fusarium* species in both pathosystems in several other countries (Galvan *et al.*, 2008; Bayraktar *et al.*, 2010; Yang *et al.*, 2009; van Poucke *et al.*, 2012). In this thesis, the diversity and the species and sub-species level identity of *Fusarium* species populations associated with diseased *Allium* and sweet pepper crops in the UK was characterised by biotypic and genotypic analysis. An attempt was made to identify molecular markers suitable for the development of a sensitive PCR diagnostic assay for detecting pathogenic *F. oxysporum* f. sp. *cepae* and distinguish these from non-pathogenic isolates and to understand pathogenicity in this fungus.

An important finding of this study was that *F. proliferatum* was found for the first time in the UK in onions with basal rot symptoms, and *F. oxysporum* was the most commonly (80%) isolated species from onion bulbs collected between the 2008

and 2010 in the UK. It was also confirmed that *F. oxysporum* and *F. proliferatum* was pathogenic on onion, although there was variation in aggressiveness. *F. solani* and *F. redolens* were found on onions grown in the UK as frequently as *F. proliferatum* (~5%), but the results of the onion seedling assay suggested that they are not causal agents of onion basal rot in the UK. Although, this needs to be confirmed by using a set of isolates more representative for these species.

More importantly, this is the first evidence that pathogenic isolates of *Fusarium* species on imported onion sets and dry onion bulbs shows can be introduced to the UK. These results suggest that new outbreaks of *Fusarium* might be caused by the import of diseased onion sets, and hence suggest that closer inspection of such planting material is required.

Moreover, this thesis contains the first report of *F. culmorum* and *F. avenaceum* from greenhouse-grown leek showing crown and basal rot symptoms and also the first evidence of *F. proliferatum* and a new sequence type (ST7) of *F. lactis* in association with internal fruit rot of sweet pepper in the UK. Although, the role of these species in disease development is yet to be confirmed.

Previous studies gave a good indication of the diversity of the worldwide population of *F. oxysporum* f. sp. *cepae* (FOC), but none of these included UK isolates (Galvan *et al*., 2008; Swift *et al*., 2002; Bayraktar *et al*., 2011; Southwood *et al*., 2012). Cladistic analysis based on translational elongation factor (*TEF*) sequences of *F. oxysporum* f. sp. *cepae* isolates from various locations with reference to other formae speciales confirmed that British isolates formed two main clades, Clade 2 and Clade 3 having been determined by O'Donnell *et al*. (1998a). Results of the sequence analysis of *TEF* suggest that *F. oxysporum* isolates associated with onion basal rot in the UK are composed of at least nine different sequence types

(STs), but only three of them (FoA, FoB and FoD) were found aggressive in onion seedlings. Isolates classified as belonging to sequence types (STs) FoA, FoB and FoD cluster closely, suggesting a clonal origin of these groups. The diversity of isolates from *Allium* species indicates the polyphyletic origin of FOC, suggesting that pathogenic ability may have evolved convergently.

A set of *F. oxysporum* isolates representing *F. oxysporum* ff. spp. *cepae, lycopersici, pisi, medicaginis, asparagi, freesia, dianthi, gladioli* along with non-aggressive isolates recovered from onion and biocontrol strain Fo47 were further characterised using four housekeeping genes and six microsatellites. Unfortunately, only some of the sequence types or microsatellite patterns could be linked to aggressiveness in onion seedlings, therefore they were not suitable molecular markers for the development for detecting FOC. The set of isolates used in this study provides an invaluable culture collection applicable for future development for breeding resistant onion varieties and to be used in studies on understanding the host specificity of this fungus.

Previous studies reported the presence of effector genes in three formae speciales, which provided a robust identification method (Lievens *et al*., 2009, Chakrabarti *et al*., 2011; Meldrum *et al*., 2012). This is the first report of the discovery of a homologue of an effector gene, *SIX7*, in FOC. Extensive screening of *F. oxysporum* isolates from *Allium* crops for the presence of *SIX7* homologues led to the discovery of *SIX7*'s limitation to one clonal lineage of FOC, the most commonly occurring clonal lineage FoA (78%). Primers developed based on polymorphism in the *SIX7* homologue of FOC (*Foc-SIX7*) offer an opportunity for the specific detection of this group, although *Foc-SIX7* was present in most isolates belonging to

FoA, but not all. This suggests that *Foc-SIX7* is not necessary for pathogenicity of FOC.

Latest publications often use whole genome sequencing to discover homologues of published effector genes and or candidate effector genes (Haas *et al*., 2009; Baxter *et al*., 2010). To date twelve genome sequences of *F. oxysporum* have been published (Broad Institute, Thatcher *et al.*, 2012). This is the first genome sequence of a FOC isolate (Fus2), which provides a novel resource to enhance our understanding of the *F. oxysporum* – non-model plant interaction. FOC genome led to the discovery of the homologues of *SIX3*, *SIX5, SIX7, SIX9* (effector genes) and pisatin-demethylase (virulence gene). This is the first report of the discovery of a homologue of *Fol-AVR2* (*=Fol-SIX3*) and *Fol-SIX5* in FOC Fus2, another f. sp. than *F. oxysporum* f. sp. *lycopersici* (FOL). Using bioinformatics tools a set of genes coding secreted proteins were identified in the genome of FOC Fus2 which are absent in the genome of tomato pathogen FOL 4287. These genes are predicted to be involved in degradation of plant material, chitin synthesis or have unknown function. Screening of ten of these candidate effector genes among a set of isolates representing various formae speciales identified suggests that the more of these genes are present in a *F. oxysporum* isolate it is the more likely to be aggressive in onion seedlings, which may imply that FOC lineages may also have different pathogenic properties. One candidate effector gene (g463) of FOC Fus2 with unknown function was found promising for the specific identification of FOC isolates based on this preliminary data.

6.2 Future prospective

A promising molecular marker, *g463*, has been identified based on the analysis of genome sequence of FOC Fus2 and initial screening of 21 *F. oxysporum* isolates from diseased *Allium* species and different formae speciales. These results have to be confirmed by testing a wider range of *F. oxysporum* isolates. In case this marker found a robust way for identification of FOC, specific markers could be designed to be tested. Primers could be used for expression analysis of this gene during infection of onion, and also from infested soil, dormant onion bulb, seedlings and during grown *in vitro*. For example, TaqMan based method for the detection of FOC in soil and planting material could greatly benefit onion growers in addition to plant inspection authorities. The role of *g463* could be further investigated by deletion and over expression of this gene. Similarly, the role of homologous *SIX7*, *SIX3* and *SIX5* of FOC needs to be clarified. It would be interesting to see in case these genes are functioning in FOC whether they could be exchanged with *SIX* genes of FOL and *vice versa*.

Annotated genome sequencing of further FOC isolates could reveal the presence of further effector genes, especially in those FOC isolates which lack published *SIX* genes. Interestingly, tomato suffers from two diseases caused by two different formae speciales, namely *F. oxysporum* ff. spp. *lycopersici* and *radicis-lycopersici.* The *SIX* genes have only been found from FOL (Broad Institute, Lievens *et al*., 2009a; Menzies *et al.*, 1990). This suggests there is a possibility that there are two formae speciales present on onion. To clarify this, GFP-labelled isolates of each forma specialis could be engineered to investigate how and which organ or tissue of the host are infected and colonised.

Bioassays defining host specificity of FOC isolates could reveal that they possess a threat to and other crops or that FOC could survive and spread by infecting other hosts, such as weed species (Abawi and Lorbeer, 1972). Based on genome sequence data of FOC Fus2, tomato, pea, alfalfa, asparagus and *Arabidopsis* could be good candidates for initial screening. Host specificity of FOC would greatly enhance our understanding on the pathogenicity, epidemiology and maybe even evolution of this fungus or pathogenicity related genes and chromosomes.

Effectors, enzymes and transcription factors important for the pathogenicity of FOC could be found by transcriptomic analysis of total RNA of FOC grown *in vitro* and during infection. This method might help to find resistance genes of onion. Moreover, the comparison of epigenetic differences to differences in pathogenicity could also help us to understand why some isolates having *SIX* genes were not-aggressive in onion seedlings.

Molecular markers applicable for the detection and identification of FOC could help the investigation of the connection of disease severity and amount of FOC propagules or the expression of pathogenicity related genes in soil, onion, crops grown in rotation with onion and weed species.

Molecular markers developed during this work provide a quick and reliable identification of *Fusarium* without any prior knowledge of *Fusarium* taxonomy. For example, *Fusarium* species associated with internal fruit rot of pepper were identified by using a newly developed primer pair targeting *TEF* (exTEFfor/FUexTEFrev). The cost and time of this work could be further reduced by using *Fusarium* species-specific primer pairs. *F. lactis*-specific markers have not been published, but by utilizing the multiple sequence data generated during this work and being generated (by C. Grant, Warwick University) could be useful to

design *F. lactis* specific primers. Additionally, it would be helpful to clarify the pathogenicity of *Fusarium* species associated with internal fruit rot in the UK and compare results of this with multiple sequence data generated. This way the economically devastating *Fusarium* species could be identified from environmental samples, such as planting material, hydroponic system and rock wool.

Survival index: Percentage of surviving onion seedlings (angular transformed data)
Isolates are considered very aggressive when they are not significantly different from Fus2 treatment (positive control)
Isolates are considered non-aggressive when they are not significantly different from Fo47 treatment (negative control)
Isolates are considered aggressive when significantly different from Fo47 treatment (negative control)
Isolates are considered non-aggressive as not significantly different from Untreated (water immersed)
*: experimental error, non-inoculated, data ignored
50x: spore concentration 50x diluted compare to other treatments ($2*10^4$ CFU/ml)
